Metabolic and chemical toxins, such as occur in gout diabetes, and plumbism, are etiological factors. The pressor effects of overindulgence in tobacco is in my judgment a frequent exciting cause of an attack. Alcohol probably plays a definite rôle, although the studies of Cabot seem to disfavor such an opinion. Of the immediate exciting causes, sudden increase of blood pressure occasioned by mental worry, sudden grief, great strenuousness, that is, bodily labor strain, rapid walking especially against a resistance, such as the ascent of a hill, hurrying upstairs, running to catch a train, heavy lifting, leaning over to button the shoes, facing a strong wind, sudden exposure to intense cold, straining at stool, and heavy eating followed by exertion, especially at night, are among the more important exciting causes.

One of my associates, age 52 years, a splendid physician, was taken at midnight, after eating a very hearty meal, with intense, agonizing pain beneath the middle of the sternum. The pain was then referred to the left shoulder and down the arm in the ulnar distribution, he was bedewed with cold perspiration and looked desperately ill. With amyl nitrite and morphine relief came, after which he vomited a large quantity of undigested food. At 8 A. M. the following morning he was seized with a second attack, which seizure I observed. He was sitting upright in bed, ashen, features fixed, pulse regular in rhythm, 70 per minute, no dyspnea, respiration slow. The pain was substernal and extended to the left arm and fingers. The attack passed off with vomiting. At noontime of the same day he suddenly expired.

Some 18 years ago, a patient was sitting in my office. He was very pale; his right hand was placed across his chest; he was absolutely fixed in position, being well bent forward; there was no shortness of breath or cyanosis. He could scarcely utter a word. He was assisted to my private office and received 1/25 gr. of nitroglycerin with inhalations of amyl nitrite. In a few moments he seemed much relieved. He then stated that he had eaten a very hearty breakfast and noticed soon thereafter a severe pain of grinding, pressing character beneath the manubrium which increased in severity so that he had great difficulty in reaching my office. With assistance, he was carried upstairs and placed in bed. His pulse was regular and 68 per minute. The attack seemed over, and he spoke of going home. Just one-half hour later, a second attack occurred in which he expired, probably from sudden vagus inhibition or coronary artery thrombosis.

Symptoms.—Angina pectoris is of interest because of the fact that the objective findings are entirely predominated by the subjective sensations and symptoms. Pain is the great subjective feature of an attack of angina; the other symptoms are simply

grouped around it. It varies in intensity from slight substernal uneasiness to the most overwhelming and terrible anguish. The pain of angina pectoris may come on so abruptly and be of such an intense, agonizing character, that fatal syncope occurs almost immediately, such as it does with a knock-out blow over the solar plexus, the patient dying as if intensely shocked. Death in such cases is probably due to complete vagus inhibition. I have observed three such examples. One was a physician who returned to his home after a strenuous forenoon's work. He was suddenly seized with a most excruciating substernal pain and constriction radiating to the left arm and shoulder, followed by great pallor and bedewed with large beads of perspiration. His face was fixed and he looked as if struck with death. His respirations were slow and pulse regular, full, compressible with a rate of 60. amyl nitrite, nitroglycerin, and one-half grain of morphine brought relief. While my finger was on the radial, it suddenly ceased beating, the heart action ceased, he turned intensely pale, his breathing stopped and his pupils immediately became widely and evenly dilated. He was dead in the twinkling of an eye, "cardiac inhibition."

Another case was a man, aged 68 years, whom I had seen in many minor attacks. He was taken suddenly at midnight with a most atrocious attack of terrible anguish, with a crushing, squeezing sensation and with the sense of impending dissolution. He was temporarily relieved with amyl nitrite and morphine, and while my finger was on the radial, the rate of which was 66, perfectly regular and of good volume, the beat suddenly ceased; the patient gave a sudden deep sigh, turned marblelike in color, and was dead in less time than it takes to describe it.

A third case was a male, aged 72 years, who gave a history of severe substernal pain and dispnea on exertion. He had a systolic pressure of 190 mm.hg. and diastolic of 110 mm.hg. I was sent for in haste to his home. He was sifting in a chair, with ghastly white coloration of his face, with his right hand clutching his left breast, complaining of the most intense crushing pain beneath the middle of the sternum; his pulse, apart from a few ectopic beats, was regular and slow. Amyl nitrite and glonoin were pushed, but without relief. I then gave him one-fourth grain of morphine. Within three minutes his pulse suddenly ceased, and a few seconds later he fell forward to the floor dead. The postmortem showed enlargement of the whole heart, fibroid myocarditis, extensive atheroma of the aorta, especially marked at the base, and with extensive narrowing of the mouths of the coronaries, with great thickening and tortuosity of those vessels.

I am familiar with pain of no greater intensity or presenting such terrible anguish. Senac has rightly said: "to have any other malady is to be sick; to have this is to be dying." The attacks both of angina minor and major are nearly always preceded by some unusual mental or physical strenuousness, or plays the part of the so-called attack of indigestion, or follows emotional excitation. They are paroxysmal in nature, but may recur so frequently as to produce the condition known as "status anginosus." Vague uneasiness and discomfort in the region of the sternum usually mistaken for indigestion may for long precede the onset of the severe attacks. A pain, be it mild or severe, referred to the thorax and excited by exercise against a resistance, is practically always angina pectoris. Let me warn you to beware of the so-called attack of indigestion, coming on in individuals suffering from arteriosclerosis with or without hypertension which may follow active exercise or strain. I have never seen a death from an attack of true indigestion, but have seen several deaths with the above described symptoms so diagnosed, with, at autopsy the usual pathological findings incident to angina pectoris. The pain is variously described by the sufferer as of a boring, tearing, constricting, stabbing or crushing like character, as if the sternum was being crushed toward the spine, or as if they were squeezed as in a vice, a sense of great oppression. It is often in fact, generally accompanied, especially in the major type of an attack by a frightful sensation of impending dissolution—angor animi. Sometimes there is a sinking sensation as if the heart was about to cease beating, and ofttimes accompanied with faintness, or a fatal syncope may ensue, or rarely the patient may pass into an unconscious state from cerebral anemia. A case in point was a lady seen in consultation, who had severe pain in the epigastric region which soon passed to the region of the sternum and into the left side of the neck and down the left arm. She felt very faint and stated that she felt sure she would die. She had no stomach distress and no nausea or vomiting. Her physician who saw her in the attack stated that she appeared in great agony was as pale as marble, with very pinched facial expression; her pulse was 90 and regular. Repeated doses of nitroglycerin together with inhalation of amyl nitrite relieved the paroxysm (angina abdominalis et pectoris).

Radiation of the Pain.—The pain may radiate to the upper chest, frequently to the scapulæ, lower jaw, occipital region, to the left or right shoulder, arm, forearm, and fingers, usually following the distribution of the ulnar or internal cutaneous nerves, or the pain may simultaneously pass to both right and left upper extremities. Occasionally the pain starts in one or the other testicle or in a lower extremity. After the attack passes off, the extremity involved is often weak, numb, cold, and dead, and cases are on record—owing to the repetition of the attacks of referred pain—where atrophy of the muscles of the extremities has occurred. Eichorst has reported a remarkable case with such muscular atrophy.

In rare instances of which I have observed three striking examples, the pain first began about the middle of the upper limbs in the region of the elbows and then radiated to the precordial region. This experience is not unique, as Heberden long ago pointed out that pain in the arms may precede the precordial anxiety, and Osler has reported some notable examples. Not infrequently, the pain of angina pectoris begins in the upper abdomen and proceeds to the chest, or proceeds in a reverse order, or it may be confined to the upper abdomen, when it is known as angina abdominalis.

Over the region in which the subjective sensation of pain is experienced, there is nearly always hyperesthesia and tenderness along the course of the vessel walls often occurs. This exalted sensi-

bility—first accurately studied by James Ross, and later elaborated by McKenzie, Head, and Gibson—is most commonly found in the distribution of the lower cervical and upper six dorsal segments. Irritation by pinching or pressure in the region of the hyperesthetic zone may reflexly excite another attack. Hence the importance of care in examining the chests of patients who have just passed through an attack of angina.

January 26, 1918, Mrs. C., employed at the Samaritan Hospital, a sufferer from severe angina pectoris and a patient of Dr. Schuyler Martin, had a severe attack of substernal pain, as if a knife were passing through her chest. The pain extended into the left shoulder and down the outer side to the left arm and radiated to the left side of the chest. While in the attack, her features were fixed; she was exceedingly pale; her pulse rate was 90 and perfectly regular; and there was no air hunger. The attack lasted about twenty minutes. Relief came from repeated doses of nitroglycerin and a small dose of morphine. The next morning, upon careful examination, the heart's action was found perfectly regular; the cardiac area was difficult to outline, owing to a very large breast. The aortic second sound was greatly accentuated and heard over an unusual wide area. There was a zone of hyperesthesia extending from the third to the sixth rib and reaching from the sternum in front to the spine behind. This hyperesthetic zone also included the skin of the outer side of the arm and forearm, together with the little and ring fingers. She states that the little and ring fingers felt dead, as she expressed it, "like wooden fingers."

Angina Abdominalis.—January 2, 1918, I was consulted by a lady, 60 years of age, with hypertension and an enlarged heart with a ringing aortic sound. Tracings showed no alternation. Her pulse was regular and 68 per minute. She had had a few days previously a very severe pain of a constricting like character, beginning in the middle of the abdomen and then radiating to the sternum and into the left shoulder. She thought she would die in the attack. Nitroglycerin relieved the paroxysm (angina abdominalis et pectoris).

These are the cases par excellence that are often unluckily diagnosed as indigestion, gastric ulcer, gall stone disease, appendicitis, pancreatitis and the like, and not so rarely submitted to unnecessary surgical intervention. Levin and Tranter report from the medical and surgical services of the Peter Bent Brigham Hospital two such cases observed in 1916 giving the signs and symptoms of an acute surgical condition of the upper abdomen. One of these patients died on the operating table within 24 hours after admission, and the other, who was not operated upon, died within 48 hours. Post-mortem showed in both cases similar findings, extensive myocarditis and coronary sclerosis. Both showed infarctions of the heart secondary to a thrombus in the anterior coronary artery whose lumen was almost obliterated, together with numerous necrotic foci. "The first case was too summarily dealt with surgically."

In the autumn of 1912, I was one day hurriedly called to see a gentleman 84 years of age, a former banker, who was having a very severe abdominal pain of a boring, constricting character between the umbilicus and ziphoid. He appeared much shocked, was extremely pale, and thought he was going to die. Within three months he had at least a dozen such attacks, all of which were relieved with repeated doses of nitroglycerin. Although the subject of marked arterial changes, the systolic pressure never ranged above 150 mm.Hg., and his heart action was perfectly rhythmical, his pulse of good character, but a little rapid. He died later on in the winter of pneumonia.

Respirations.—The respiration in true cases of angina pectoris—unless associated with marked emphysema, asthma, or bronchitis, or serious cardiac disease with myocardial insufficiency—is during the attack very little disturbed. There is rarely distinct air hunger; the respiratory movements may be fewer in number, and the patient often instinctively fails to breathe full and deep, for fear of increasing the heart pang. In some cases the respirations are increased in number. Cheynes-Stokes respiration is usually a harbinger of a fatal issue.

The so-called cardiac asthma with marked dyspnea, accompanied or not with pulmonary congestion or edema occurs only in the cases of angina associated with serious heart complications. In this connection, John Hunter's description of one of his own paroxysms is interesting. It began with a sense of tightness in the muscles of the neck, face, and left jaw, and then passed down the arm to the thumb. Retrosternal pain occurred simultaneously as if the bone was being crushed and pushed towards the spine. Fearful pain in the throat occurred, so that he was afraid to swallow. His respirations were shallow, and no air hunger existed throughout the attack.

Attitude.—During the attack, the patient usually assumes a fixed attitude—sitting or standing with the trunk bent forward the head more or less fixed, often with one of the hands over the chest or præcordium, or both resting on the knees, fearful that the slightest motion may increase the pain, as occurred in a fatal case under my care. Occasionally, however, the patient paces the floor with great agony unable to obtain relief. Toward the close of an attack, they often belch gas freely and sometimes develop troublesome hiccough.

Pulse.—The pulse in many cases of angina pectoris remains throughout the paroxysms perfectly regular in rhythm, not at all or slightly accelerated; frequently the pulse is slower than normal. I once observed a case of angina pectoris associated with the Stokes-Adams syndrome with complete loss of consciousness during the anginoid attack. The radial arteries may feel dull and dilated, or small, hard, and wiry. Sometimes, however, the pulse is rapid, irregular in rhythm, feeble in volume and easily compressed. Extra or ectopic beats are not at all infrequent, and the pulsus alternans occurs quite frequently. These types of irregularity associated with angina pectoris are usually found, as emphasized by MacKenzie, in sufferers from cardiacsclerosis with myocardial insufficiency and this is particularly true of cases with pulsus alternans, a type of arrythmia which betokens myocardial exhaustion and early death. I have twice observed cases of fatal angina, the result of recurring paroxysms "status anginosus," extending over a period of several days, develop a number of hours before death, typical alternating pulse and Cheyne-Stokes respirations. If the attacks become complicated by occulsion of the larger branches of the coronary arteries, then the pulse becomes rapid, irregular, and easily compressed, with a sudden fall of systolic blood pressure, sustained diastolic pressure and symptoms of myocardial insufficiency early develop.

Blood Pressure: The systolic pressure at the onset of the attack nearly always rises beyond the normal level found in the interval between the paroxysm. The

following case of angina well illustrates this point:

A patient 62 years of age, with hypertension and general arteriosclerosis, a sufferer from many attacks of angina, had carried an average systolic pressure of 160 mm.Hg., with a cuff in place, I noticed a sudden systolic rise to 175 mm.Hg. His face became pale, his features fixed, and he stated that he was in severe substernal pain which had passed into the left shoulder and down the left arm in the distribution of the ulnar nerve. One-fiftieth grain of glonoin was administered, and in two minutes the systolic pressure rose to 185, in five minutes it dropped to 170, and in ten minutes to 150, when the paroxysm had ceased.

The blood pressure, however, is by no means, as frequently quoted, always high; it may remain normal or even drop below normal. In one of my severe cases of angina without discoverable cardiac disease the systolic pressure during the attack was 160 mm.HHg., diastolic, 90, pulse was 70 and perfectly regular, the respirations were rather slow. After the passing of the attack the systolic pressure dropped to 130 mm.Hg. Following this paroxysm he had a series of attacks lasting four days "status anginosus," and finally died of pulmonary edema. His systolic pressure never again rose above 120, the pulses became rapid and irregular, and he suffered from dyspnea and cyanosis, "coronary thrombosis."

In a case which I saw last summer of a railroad man, 62 years of age, who for a period of two years had been the subject of mild attacks of angina, manifested by substernal pain extending into the left shoulder and arm, was suddenly seized, after a long automobile trip (having driven his own car), with excruciating substernal pain, with great pallor and sense of impending dissolution, which was only relieved by repeated doses of nitroglycerin and one-half grain of morphine hypodermically. Two days later, having in the interim suffered no precordial anxiety, he was taken with another attack, though milder in character. Soon thereafter he became very dyspneic, was cyanosed, very nervous and restless, and unable to sleep. His facial expression was pinched and pale, with the lips violaceous, his pulse which before had been regular and slow "rate 68" and his systolic blood pressure registering 190 mm.Hg., was now rapid "120" and very irregular; his systolic pressure had dropped to 110 and his diastolic remained at 70. His heart action was tumultuous, and a soft systolic murmur was heard at the apex faintly conducted to the left, "relative incompetency." Many large subcrepitant rales were heard at the bases posteriorly. It was my opinion that, following the onset of the second attack of angina, a large branch of one of his coronary arteries became plugged with an embolus or thrombus and accordingly made a very grave prognosis. I saw him two days later and found him *in extremis* with all the above mentioned symptoms greatly exaggerated, and in addition, a localized fresh pericardial friction rub was present, heard best over the body of the right ventricle at level of the fourth costal cartilage. He died the following day, and despite our entreaties no postmortem examination was permitted.

The interesting feature of this case were the sudden onset following an anginoid attack, of grave myocardial insufficiency and auricular fibrillation, sudden and permanent fall of the systolic blood pressure, sustained diastolic pressure, development of relative mitral incompetency, and the sudden appearance of a localized pericardial friction rub, doubtless due to an infarct of the heart localized just beneath the epicardium. James B. Herrick, who has observed and published several cases of coronary artery thrombosis, has shown that in electrocardiograms taken from three cases the T-wave is invariably inverted. His colleague, L. F. Smith, has obtained in dogs similar inversions of the T-wave after ligating the main branches of the coronary arteries.

Sir Clifford Allbutt in his work on diseases of the arteries and angina pectoris described a similar case to the above, with autopsy, in which a large, fresh red thrombus was found in the right coronary artery extending almost to the junction of the transverse and posterior descending branches.

I have previously seen two cases with similar symptoms to the one above described, each following a status anginosus with death, which were in my judgment due to a coronary thrombus plugging large branches, with consequent infarctions of the myocardium. In each case a few hours after the onset, a localized pericardial friction rub was present and remained until death.

Subdivision of Angina.—True angina may simply be subdivided into minor and major attacks much in the same way as we classify minor and major attacks of epilepsy. I am strongly convinced that the term "pseudoangina pectoris" should be excluded from the classification of the anginas. Obviously we are dealing with true angina pectoris, or we are dealing with a pain of a paroxysmal character, which for the lack of careful differentiation has been labeled with the unwarranted title of "pseudoangina pectoris," namely, reflex angina pectoris, neurasthenic angina pectoris, the hysterical type, and the angina vasomotoria of Nothnagel. The latter type may have a definite pathological physiology and, therefore, should with justice be placed in the category of the true angina pectoris. The symptoms of this latter type, according to Nothnagel, are sudden onset with coldness and lividity of the extremities, with great general pallor, profound cold perspiration and faintness, followed by the usual symptoms that we are so accustomed to observe in angina pectori; organic in type, but Nothnagel insists that this type occurs without any structural changes in the heart or blood vessels. He explains this complex on the assumption of a general vasomotor spasm together with a spasm of the coronary arteries. I must confess, though having had considerable experience with the complex angina pectoris, I cannot recall having seen such an example.

Theories of the causation of the pain.—The numerous theories offered in explanation of the pain in angina pectoris are legion, and they only serve to indicate our shortcomings as to the exact causative factor of its production. The following are a few of the many explanations thus far given:

1. Ischemia of the heart muscles from vasomotor spasm intermittent claudication.—Allen, Burns, Potain and Osler.

2. Sudden acute dilation of the heart with the production of pain similar to that of intestinal colic from local distention of the bowel.—Lauder Brunton and Traube. How frequently, however, does one observe clinically very grave forms of acute dilation of the heart with arryhtmia, fibrillation or flutter, great dyspnea, pulmonary congestion, and edema and various other symptoms that accompany decompensation without the slightest evidence of anginoid pain.

3. Neuritis of the cardiac nerves or the superimposed cardiac ganglia.—Lancereaux and Peter.

4. Neuralgia of the same named structures.

5. Neuritis of the phrenic nerve.

6. Impairment of the contractility of the heart muscle fibres the pain being due to a viscerosensory reflex.—MacKenzie.

7. Heberden and Latham attributed the pain to spasm of the heart, a most fanciful and, in my mind, absurd theory.

Many clinicians have listened to the heart during paroxysms of angina pectoris and have been convinced of the presence of the normal mechanism of the heart's action. They have observed the presence of the recurring impulse and heard the heart sounds repeat themselves. Regular successive spasms of the heart would be incompatible with life and no evidence of cardiac activity would be present. I have never read where at autopsy of a true case of angina pectoris the heart was found in systolic contraction.

The theory offered by Sir Clifford Allbutt seems the most rational explanation of the pain of angina pectoris thus far presented. Briefly, it is as follows: With the onset of an attack of angina pectoris there is a sudden rise in the intra-aortic pressure with sudden aortic distention which causes an irritation of the sensory terminal end organs located in the suprasigmoid part of the aorta, thus exciting both the local and referred, pain of angina pectoris. This portion of the thoracic aorta is likened by Prof. Allbutt to a sensitive tambour regulating cardiac energy by the intermediation of the vagus, and it is diseases of this particular area that are most prone to be associated with anginoid attacks. Sir Clifford Allbutt also states that he has never failed to find in a case of unmistakable angina, regardless of the state of the coronaries, disease of the suprasigmoid part of the aortic arch. This area is abundantly supplied with sensory afferent nerve fibres, and Dogiel and his pupils have found sensory end plates in the adventitia and other parts of the aortic wall. In this connection I desire to direct attention to the similarity of the pain of angina pectoris to the severe agonizing pain and the attending shock which often accompanies the sudden plugging of a large arterial trunk like the iliac, femoral, subclavian, axillary, brachial, or popliteal. I have reported a number of such examples, and I have no doubt that many of you have had similar experiences. The pain is probably due to the sudden distention and consequent irritation of the sensitive nerve terminals of the arterial wall just proximal to the point of attachment of the coagulum, either embolic or thrombic in character.

Prognosis.—The mortality of angina pectoris must of necessity be very high. I have witnessed at the bedside fifteen deaths from this disease. The very fact of the presence of so many cases of that dreadful oppression and sensation of impending dissolution (angor animi) together with the awful dread of the renewal of the attack, gives us a sort of key to the probable outlook of those afflicted with this mortal complaint. Death is not so rarely due to coronary arterial thrombosis; death may be sudden, or it may occur after several days of suffering.

Charles Sumner said: "This treacherous disease produces in my mind a positive uncertainty—when I go out of my house whether I shall ever enter it again a live man." You may recall the remarks of John Hunter who used to say that his life was in the hands of any rascal who chose to annoy and tease him, and you probably remember the heated discussion at that last faculty meeting which precipitated his fatal attack. It must, however, be remembered that not every sufferer with this complaint succumbs. I have known of several recoveries and recall to mind one of my esteemed confrères, the late Dr. Akin of Troy, who had as many as 100 attacks, mild and severe, when he developed, from his associated myocardial changes, a relative mitral insufficiency that so relieved his aortic pressure that he never thereafter experienced an attack. He died some years later of the results of the attendant myocardial insufficiency.

Angina pectoris, curiously enough is rare in sufferers with well-marked mitral regurgitation. The explanation probably lies in its effect in preventing high aortic pressure. Notable examples of such relief with the establishment of a relative mitral leakage are in the literature, and I have witnessed several such cases.

The cases due to tobacco, alcohol, gout, diabetes, and other metabolic toxins usually cease with the elimination of the toxins incident to them.

The prognosis is especially favorable in the large number of cases, if early recognized, having their origin in syphilitic changes of the aorta—coronary area, "suprasigmoid aortitis." Intensive and long continued antiluetic treatment often cures. I have seen several such examples where remarkable relief and cure came from active therapeutic interference. Dieulafoy cites several cases of severe angina pectoris with a luetic basis where repeated injections of half a centigram of mercury biniodide produced remarkable results.

Each case must be a study unto itself, and the prognosis based accordingly, remembering always to carefully guard the outlook. It is wise always to inform some member of the family or near relative as to the exact prognostic outlook. It is, however, exceedingly unwise to go into too great detail with the patient in regard to his case unless you are thoroughly well acquainted with his mental attitude or make-up.

Treatment.—No greater or more responsible duty confronts the practitioner than to properly guide and treat the patient who suffers from angina pectoris. Each case should be studied from every possible angle. We should be familiar with the condition of the myocardium, the cardiac reserve, the condition of the vessels and the blood pressure, the renal functioning, the condition of the gastroenteric tract, the amount of sleep, the exact character and amount of work, whether physical or mental, the habits of the patient as to excesses in eating, drinking, and smoking, and the presence of any constitutional disease or vice which predisposes to angina, such as gout, diabetes, or nephritis. We should be fully conversant with the character and frequency of the attacks and whether they are of the mild or major type. The exact exciting cause of the attack should be carefully sought in each case and, if ascertained, rigidly prohibited. The question of syphilis, because of the rôle which it plays in the causation of this complex should be most carefully investigated and a Wassermann reaction should be carried out in each case, so that early intensive antiluetic treatment may be instituted. The pa-

tient should be properly advised in regard to the selection of diet. He should be urged to eat sparingly and warned never to exercise directly after a meal, or to eat heartily at night, and the use of tobacco should be limited or absolutely prohibited. He should have the maximum amount of rest, with freedom from worry and anxiety. Exercise should be limited to moderate walking on the flat, short of producing precordial distress, dyspnea, or fatigue. Carriage or automobile riding is permissible. If possbile the winters should be spent in the South, so as to avoid the inclement weather of the North. For the paroxysm, the nitrites so long ago pointed out by Sir Lauder Brunton, are almost specific, although one sees now and again a case where they actually fail to bring relief. I am fond of using at the onset inhalations of amyl nitrite, and this to be quickly followed by good stiff doses of nitroglycerin, and don't be afraid to use it. I prefer to use the one per cent. alcoholic solution dropped just beneath the point of the tongue in the sublingual region. If relief does not speedily come from the nitrites, then recourse should at once be had to morphine and atropine. This latter drug will also help to stave off vagus inhibition. Additional doses of atropine should always be used if faintness, marked slowness of the pulse or an intense feeling of impending death should come on, for it is generally believed that those sensations are in part or wholly due to vagus inhibition. Atropine dilates the peripheral vessel and probably the coronaries.

One marvels at times, in gouty patients, with the relief that comes and the increase of the interval between the attacks or their complete cessation, following the use of colchicum with eliminants.

Well do I remember a case of a man who had had repeated minor attacks of angina while suffering from gouty manifestations, which were entirely relieved with colchicum an occasional blue pill, plenty of water, and the citrates. He died, however, some years later, from myocardial insufficiency following a status anginosis—coronary thrombosis.

I have never seen any remarkable effects from the use of theobromin or the caffeine products given with the idea of improving the coronary circulation through vasodilatation.

Chloroform inhalations sometimes may give the only relief in severe anginoid paroxysms. I remember the case of a prominent clergyman, a great sufferer from angina, whose only relief came from chloroform inhalations, though the nitrites, morphia, stimulants, antispasmodics, and other sedatives, had been frequently used.

Cases of angina associated with or followed by myocardial insufficiency, particularly those cases associated with auricular fibrillation, flutter, or alternation, should receive digitalis until relieved and then be treated for long periods of time with small tonic doses.

After the paroxysm passes the patient should be advised to rest absolutely for a period of several days, and should be carefully coached in regard to diet elimination, exercise, and work.

The iodides, administered for long periods of time, are of unquestionable value in the treatment of angina pectoris. They lessen the severity of the pain and widen the interval between the attacks, and in some instances cause their cessation.

I have had no personal experience with the use of blood letting in angina pectoris. Some clinicians, however, are in favor of it in the hypertensive cases associated with angina pectoris.

AUSCULTATORY PERCUSSION IN DIAGNOSIS OF CARDIAC LESIONS.*

By W. F. Milroy, M.D.,
Omaha, Neb.

Doubtless many of you are acquainted with the paper recently presented before the Council on Medical Education by General Edward L. Munson, entitled "The Needs of Medical Education as Revealed by the War." General Munson had general charge of medical department training for a year. He showed that the medical officers who finally reached the medical training camps were quite superior to the average of the medical profession of the country and yet of these men a very large number were found to be professionally not qualified. Later, in a reply to this paper, Dr. Vaughan called attention to the splendid work that has been done by these very men, by inference at least, taking exception to the severe criticism of General Munson. Although everything that was claimed by Dr. Vaughan be admitted, it cannot be denied that a large number of medical men seeking service in the army were found to be ill prepared for their work. Instructors from several of the army schools have told me personally of their astonishment at the inefficiency of these doctors in respect to physical diagnosis. Not only was this true of young and inexperienced men, but also of physicians who had had years of experience and often those who in their own communities were regarded as highly capable and enjoyed an excellent practice.

In the *Journal of the American Medical Association* of January 18, 1919, appeared a paper by George Edmeston Fahr and others, entitled "Cardiovascular Examination of Fifty-five Thousand Recruits." The work reported was performed at Camp Travis, Fort Sam Houston. These recruits were sent from Texas and Oklahoma. As a result of their observations these writers remark: "We can hardly believe that the majority of the local boards sending men to Camp Travis are capable of picking up many cases of valvular diseases of the heart."

*Read at the twentieth annual meeting of the American Therapeutic Society at Atlantic City, June 6 and 7, 1919.

Now, this recent experience of our army has not surprised me. It only confirms the opinion I have held for years, derived from personal observation.

Diseases of the heart result in as many deaths as tuberculosis, perhaps more. It is of vital importance that physicians should be able to recognize heart lesions. It seems that a large proportion of students are victims of the delusion that they have mastered the subject of cardiac diagnosis as soon as they hav elearned its rudiments, and this delusion is incurable.

What interests me most deeply in this business is not scientific accuracy in differentiating a lesion; this is interesting and commendable, but clinically of comparatively little consequence. On the contrary, it is a matter of the biggest consequence to a patient whether he has a sound heart or a defective heart that means his destruction sooner or later. I am not encouraging or excusing slovenliness in diagnosis, but in face of the existence of such general incompetence in this matter I am willing to accept a diagnosis which, if imperfect, is sufficient to serve as an indication for treatment. Such a diagnosis is the recognition of the fact that an organic lesion exists.

From the beginning students are taught to study murmurs. They try to hear murmurs, and say they hear them when they do not. I believe this often is due to the use of a bad stethoscope and its roar or squeak or jingle is all they hear. They may make out a murmur and try to discover its peculiarities. A few students learn to recognize certain of these, the balance wish they might, and let it go at that. The result is the incompetency we have been hearing about.

Now let me ask you for a time to forget that anybody ever heard a cardiac murmur. It is a reasonable and well established fact that every valvular lesion which causes a departure from the physiological functioning of the heart imposes upon some part of that organ a demand for an abnormal amount of work. Initial dilatation follows, but eventually it rises t othe occasion and compensatory hypertrophy develops. The heart is enlarged. Speaking not with absolute accuracy, but with a sufficient degree of accuracy for a working basis, it may be affirmed that every organic cardiac lesion results in cardiac enlargement; and conversely, the absence of cardiac enlargement disproves the presence of any organic lesion. Since this is true, if I am able to determine the size of the heart I am on perfectly safe ground, because I know absolutely whether the organ is sound or diseased; and if diseased, I can form an idea of the severity of the lesion and, by the aid of general symptoms, of the degree of compensation that exists. Should I determine that treatment is indicated, it will be on account of imperfect compensation and it will be immaterial what valvular lesion is responsible. I have not listened for a murmur. I know nothing about murmurs. I only know that something has gone wrong with the mechanism of this heart which has placed an abnormal demand for work upon it, or that a diseased muscle is giving way under the strain. It is my idea that better results could be attained by teaching students how to determine the size of the heart rather than to permit them to be wholly absorbed in the study of murmurs, which experinece has shown to be, to the end of their career, a babel of sound inaudible or untranslatable, or both.

Now, in the auscultatory percussion we have a method of measuring the heart which is always available, and always sufficiently exact, and proficiency in its use is readily acquired.

Examination of a dozen more recent books upon the subject of physical diagnosis shows that some of them make absolutely no reference to auscultatory percussion of the heart, some of them casually mention it, a few damn it with faint praise. To me this lack of interest is not surprising, since the method is worthless if employed as they describe it, viz., by percussion in concentric and narrowing arcs of circles about the stethoscope.

Every form of matter capable of sonorous vibration has its fundamental note. Tone or pitch must vary with the hardness or elasticity in bodies. These differences in sound depend upon fixed physical laws, and must be constant. Whenever, therefore, we find in the organs of the human body differences in tone or pitch upon percussion we may safely infer difference in structure. Every physician is acquainted with these principles, and is daily practising them. In the case of the heart, however, a tremendous obstacle is encountered in the presence of the ribs. When a percussion blow is applied over one of these the vibrations created are conveyed along its entire length, and a stethoscope applied over it will communicate the sound generated in that rib. This sound overpowers or greatly obscures any sound that may come from underlying structures. Herein lies the great obstacle that has prevented the successful practice of auscultatory percussion of the heart.

When a vibrating body is brought into intimate contact with another body it communicates to it its own vibrations, yet when these bodies differ materially in density, at each change of medium a portion of the wave is reflected and the transmitted part is refracted and the sound is stifled and obstructed. This principle holds as between a rib and its cartilage. Therefore, when percussion is performed with the instrument resting free from the ribs receiving the percussion stroke, the interference of rib vibrations is eliminated and the great obstacle in the way of auscultatory percusssion of the heart is removed.

The heart extends normally as high as the upper border of the third rib. The farthest projection of the heart to the left will always be found in the vicinity of the apex. For clinical purposes, therefore, in locating the left border it is sufficient to locate it in the fifth space. Hence, the stethoscope is placed immediately to the left of the sternum and extending upward from the fourth space. Thus located, the imperative condition also is met that the instrument must rest over a portion of the heart that is in contact with the chest wall. Auscultatory percussion is most conveniently performed with the patient in the dorsal position, the examiner at his right side. The instrument is held in the position indicated by an assistant or by the right hand of the patient with moderate pressure against the chest wall. A finger of the examiner's left hand serves as a plexímeter. It is placed in the fifth intercostal space, at a point so far to the left as to

be entirely beyond the cardiac border. The pressure of the pleximeter finger must be uniform, as it is moved from place to place toward the middle line. To secure this uniformity it is advisable that the pressure of this finger be so firm that the fifth and sixth ribs are both distinctly felt in each position of the finger. In a thin person this pressure will not be strong, but in a fat person it must be quite firm. In the latter class of cases this firmness of pressure is essential for another reason. Transmission of a percussion impulse loses little by the interposition of light solids but much if loose or badly approximated tissues intervene; therefore, light percussion over a chest wall containing a considerable thickness of adipose tissue, does not transmit to the stethoscope the percussion note of the subjacent heart unless the pleximeter finger is thus deeply pressed into it, and heavy percussion must not be employed. Writers upon the subject emphasize the necessity for uniformity of stroke in the performance of percussion, but seem comparatively indifferent to the amount of pressure exerted by the pleximeter. In my opinion the latter point is of hardly less importance than the former. As has been intimated the percussion stroke in the process I am describing must be of very moderate intensity, and it must be uniform in force. Thus inaugurated, percussion is made from left to right until the pitch of the percussion note is observed to change, the site of this change representing the situation of the left border of the heart. As was stated by the authors of the method, in reference to the use of auscultatory percussion: "The percussion sound communicated to the ear far exceeds in intensity and distinctness the same sound transmitted through the air. The slightest change in pitch and quality is readily appreciated."

In determining the situation of the right border the procedure is similar. The chest piece of the instrument is placed at the left of the sternum, at the point already mentioned. Percussion is made in the fourth space, at which level is found the greatest projection of the heart to the right. Commencing well beyond the cardiac limit, the examiner passes from right to left noting the border of the heart at the point where the change in the quality of sound first appears. Similar percussion will locate the right border at other points, if so desired.

In almost all cases of cardiac disease every purpose is served by the accurate determination of the right and left borders. However, if it seems desirable to determine the upper limit and the left border above the fifth space this may be done by placing the instrument at the left of the sternum and below the fourth rib. Likewise, the apex may be outlined when the instrument is in the position for fixing the left border in the fifth space.

The late Dr. Alfred L. Loomis, in his work on physical diagnosis stated that the first to recommend auscultatory percussion in examination of the heart were Drs. Cammann and Clark, in a publication in the *New York Journal of Medicine and Surgery* of July 1840. It was not until a month ago that I enjoyed the privilege of reading this paper. I found myself working along their lines precisely except in one very important particular, to which I shall refer. This was the Dr. Cammann whose stethoscope we have used, and it was Dr. Alonzo Clark whose signature adorns the diplomas of some of us. The paper was entitled "A New Mode of Ascertaining the Dimensions, Form, and Condition of Internal Organs by Percussion." Among other things, they claimed that "the heart can be measured in all but its anteroposterior diameters, under most, perhaps all, circumstances of health and disease, with hardly less exactness than we would be able to do if the organ were exposed before us." A review of their patient experiments is very convincing of the truth of their claims. They affirm: "We have been able to trace the outlines of the heart when the whole organ has been covered with healthy lung; when the lung over it and around it has been hepatized from inflammation or consolidated by tubercles; when, with such tuberculous consolidation, there has been remarkable thickening of the pleuritic membrane over the precordial region; when pleuritic effusion on either side has to ordinary percussion blended the cardiac and pulmonary portion of the chest into one region of unbroken dullness; when extreme effusion on the left side has crowded the heart wholly to the right of the median line upon the convex surface of the liver so as to produce uninterrupted dullness from the entire left side across the anterior right half of the chest to the hepatic region; when there has been empyema and pneumothorax of the left side; when there has been atrophy of the heart; when there has been hypertrophy and dilatation, each separately and both combined; when there has been preternatural softening and fatty degeneration; when there has been pericarditis with adhesions; when the stomach has been filled with aliment or the abdomen with food."

These writers were entitled to the confidence of the profession. Why, then, did this work fail to attract attention and the method receive no favor? I attribute it to two causes. First, because the significance of the size of the heart had not been fully realized; second, because the practical application of the method was not made convenient or easy. Cammann and Clark invented a special stethoscope with which to overcome the intervention of the ribs. It consisted in a truncated wedge of cedar wood, the other end broad, to rest against the ear of the examiner. The wedge was placed between the ribs. Their paper does not indicate that they realized the part played by the costal cartilages in respect to rib vibrations or the possibility of dodging these vibrations and still being able to accomplish the desired results.

A word as to other methods of measuring the heart. Four years ago Dr. Charles S. Williamson of Chicago, himself an internist and a teacher, presented a paper before the Medical Society of the Missouri Valley, in which he showed the inaccuracy of conclusions derived from ordinary percussion for the purpose of locating the cardiac borders. Fluoroscopic pictures displayed the errors of capable diagnosticians. Indeed, I believe no one who has studied the matter will claim that ordinary percussion is at all dependable.

Very great importance is attached to the location of the apex beat. This plan has been elaborated by Richard C. Cabot. Now, in a great many cases it is impossible to locate the apex beat and these are very likely to be the cases in which it is espe-

cially important to determine the size of the heart, for even murmurs may be absent and the case be most serious. A friend of mine, attempting a demonstration before a class, asked a patient to rise to a sitting posture and lean forward. She did so, but when she leaned forward she was dead. Usually, the left border is outside of the apex beat, but frequently the apex beat is outside of the left border.

Of course, the method of choice is the use of the roentgen ray, but this is available in only a very small minority of cases, while auscultatory percussion is available under all.

I must mention two infrequent conditions that must be excepted. One of these is an extreme degree of emphysema, with a large body of lung crowded between the heart and the chest wall. The other is found in aged persons with complete ossification of the costal cartilages. Here percussion anywhere upon any rib gives rise to a ringing sound which is carried over the whole chest as though it were a steel cage.

Nine years ago, in an article in the *New York Medical Journal*, I called attention to the advantage of auscultatory percussion of the heart. For at least fifteen years I have employed it with the utmost satisfaction. For my part, I must express emphatically the conviction that in ignoring this method of examination the profession has been depriving itself of an aid of the utmost value.

THERAPEUTIC PROBLEMS IN PULMONARY TUBERCULOSIS WITH DISTURBANCE OF THE CARDIOVASCULAR SYSTEM.*†

By ERNEST ZUEBLIN, M.D.,

CINCINNATI, OHIO

ASSOCIATE PROFESSOR OF MEDICINE, UNIVERSITY OF CINCINNATI; RESIDENT MEDICAL DIRECTOR CINCINNATI TUBERCULOSIS SANITARIUM.

In the treatment of pulmonary tuberculosis our chief aim is to arrest the clinical manifestations resulting from the local and systemic effects of bacillary infection. To what extent the pathological tissue changes can be influenced and brought to a stage of quiescence and cicatrization remains an open question which will be solved only by an observation period extending beyond the moment when the patient asks for his release from the physician's care. We all know the insidious course of the disease and realize the danger of a too great optimism in pronouncing the term of "cure" in a tuberculous individual.

It is not necessary to pass in review the treatment recommendable to incipient cases of pulmonary tuberculosis. For the hopeful patient it may seem exceedingly simple and hardly serious enough to engage the services of a physician. Particularly where distinct symptomatic signs are not very evident the patient frequently doubts the physician's foresight and correctness of diagnosis. Under the impression of having "only a slight cold" only too often the physician's advice is not followed, and neglecting the chances of a proper recovery, the patient drifts into the second or third stage of the disease. We must admit that among the patients with pulmonary lesions involving both upper lobes, partly interesting, too, the lower lobes, we find a good many optimists who never could realize that in such an infection there exists a critical period, past which all good intentions of taking the cure seriously are of no avail to check the fatal course of the disease.

In the study of pulmonary tuberculosis, of course, the minute investigation of the lungs, the character of physical signs related to the pathological process, deserves our attention, but besides this, certain disturbances bearing upon the cardiovascular apparatus deserves equally our attention. It is not surprising that, as we see in the case of other infectious diseases (diphtheria, typhoid, influenza), the heart and vessels will show abnormal function and pathological changes to a greater or lesser extent in tuberculosis. Deviations from normal function and size may appear of interest from the diagnostic standpoint, but prognostically and therapeutically more important, they deserve our attention. They may be overlooked and the physician's recommendation to the patient "all that you need is fresh air and plenty of exercise," taken too literally by the patient, may mean more harm than benefit. Supposing the patient having reached a stage of apparent quiescence and he resumes a nactivity which is incompatible with the functions of the cardiovascular apparatus, necessarily complaints of insufficient adaptation to occupation will arise.

In medical literature, to my knowledge, not very much has been said about the disturbances in the circulatory apparatus as manifested in the course of pulmonary tuberculosis. The question of an aplasia of the heart, predisposing to tuberculosis or the increasing atrophy of the heart muscle, similar to the trophic changes in the skeletal muscles, has not yet been definitely settled. In the absence of more definite knowledge on abnormal function of the heart and vessels, we have observed our cases more closely in the past two years. The results of such a study may help us in the decision whether and to what extent cardiovascular disturbances may be present.

We shall consider: (1) The heart, size, position, character of sounds; (2) the pulse, blood pressure, cardiac activity, and vasomotor changes.

In our institutional work the majority of cases belong to the second and third stages of the disease, while only a limited number of incipient cases come to our observation. With regard to the incipient cases it must be said that, even with careful physical examination and signs suggesting a first stage involvement, very frequently *x*-ray plates will show a more extensive involvement which justifies a classification of the case in the second class.

Under ordinary circumstances we are accustomed to regard the size of the heart as normal when its apex beat can be located in the fifth interspace, coincident with the midclavicular line, and when the relative cardiac dulness does not pass beyond the right sternal border, nor reach above the upper border of the third rib.

In my experience with first stage cases of ap-

*A clinical study from the Tuberculosis Department of the University and the Cincinnati Tuberculosis Sanitarium.

†Paper read before the twentieth annual meeting of the American Therapeutic Society at Atlantic City, N. J., June 6 and 7, 1919.

parently short duration, no striking change from the normal size and position could be ascertained. Later in the course of the disease, however, the lung resonance encroaches slightly upon the right sternal border, resulting in a lessened extent of the relative cardiac dulness to the right from the midsternal line. The heart sounds over the mitral and tricuspid area are usually normal in intensity; frequently accentuated, aortic sounds are normal; over the pulmonalis area, however, the accentuation of the second sound is very striking.

Second Stage Cases.—Findings of relative cardiac dulness, averages

	To Right, Cm.	To Left, Cm.	Transverse Diameter, Cm.	Height Cm.	Oblique Diameter, Cm.	Cardiac Triangle, Sq. Cm.
25 white males	1.77	8.46	10.32	7.85	11.95	40.10
25 white females	1.50	8.30	9.80	7.00	11.17	34.33

were above normal. For the height, maximum amounted to 10.9 c.m., the minimum being 4.4 c.m. In several instances the oblique diameter was found at 16.8 c.m.; relatively rarely were figures below the average, the minimum being 8.6 c.m. In ten cases the size of the heart suggested cardiac dilatation, especially in patients past 40 years of age.

Among the twenty-five female cases the extent of the cardiac dullness to the right did not exceed very far the right midsternal line; in two instances that landmark was not reached at all, only once the maximum extent of 3.3 c.m. to the right was noticed. The measures for the left diameter exceeded in ten instances the average figure, the maximum being 10 c.m., the minimum 6 c.m.; also for the height in about fifteen cases the calculated average was surpassed, the maximum reaching 8.5 c.m., the minimum 4.5 c.m. The oblique diameter was greater than the average in thirteen cases, a maximum of 14 c.m. and a minimum of 8.5 c.m. being noted. In 10 cases the signs suggested cardiac enlargement.

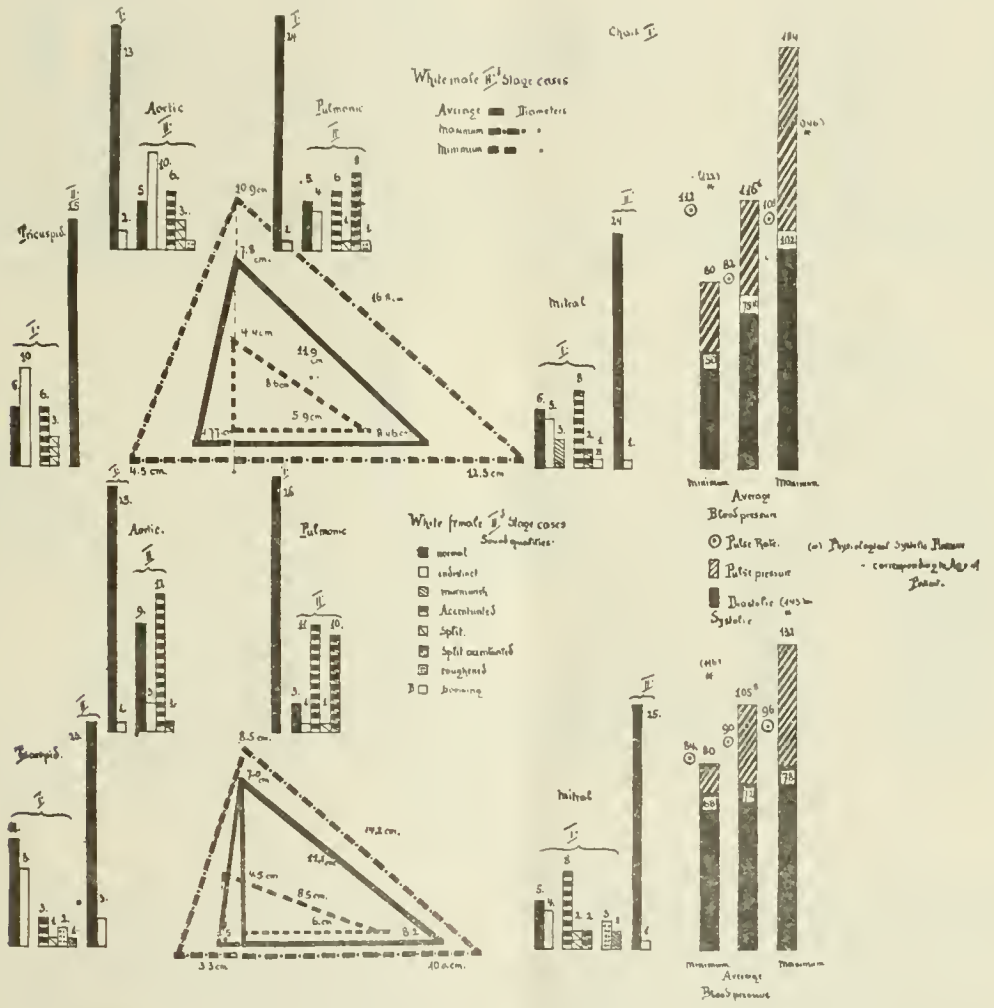

CHART I.—Second-stage cases.

In the white male patients the cardiac dulness coincided only in four instances with the right sternal border, in five instances it reached 4.5 c.m. past the midsternal line; only exceptionally it did not surpass that landmark. The maximum and minimum readings for the left side were 12.5 c.m. and 5.9 c.m. respectively; in eight instances the figures

A glance at the table will show that normal heart sounds over all valvular areas are not frequently encountered. The second mitral and tricuspid sounds, as well as the first aortic and first pulmonic sounds will not show very marked deviations from the normal. The accentuation of the first mitral sound appears frequently present in still robust

and young patients, while indistinctness, splitting, murmurish qualities are encountered in debilitated and chronic fibrous patients. Accentuation of the first tricuspid sound is not frequent, and the indistinct quality is often present. Furthermore, I wish to call attention to the indistinct character of the second aortic sound, an accentuation being less frequently observed. A few words about the qualities of the second pulmonic sound may be added. Very rarely the sound is normal; accentuation and accentuated split second sounds appear frequently; in a few instances the sounds were very weak. As regards the female patients, normal heart sounds are not frequent, although instances of abnormal quality of the first tricuspid sound are less striking. Occasionally the murmurish and roughened character of the first mitral sound as well of the first tricuspid may be present. Accentuation of the second aortic sound with reduplication is often present, and this is particularly striking for the second pulmonic sound.

Twenty-five Males.

	Mitral.		Tricuspid.		Aortic.		Pulmonic.	
	I.	II.	I.	II.	I.	II.	I.	II.
Normal	6	24	6	25	23	5	24	5
Indistinct	5	1	10	..	2	10	1	4
Murmurish	3	..		..	..	.	..	[illegible]
Accentuated	8	..	6	..	.	6	.	6
Splitting	..	.	3	.	.	3	..	1
Splitting, accentuated	2	.		.	[illegible]	.		8
Roughened						1		1
Booming	1						..	..

Twenty-five Females.

Normal	5	25	11	23	25	9	26	3
Indistinct	1	1	8	3	1	3		1
Accentuated	8		3	..		12		11
Splitting	2		1	..			..	1
Splitting, accentuated	2			..		1	..	10
Roughened	3	.	2	.		1	..	..
Murmurish	2		1	..		..	..	..

Third Stage Cases.—The averages of the extent of the relative cardiac dullness are summarized in the table below.

	To Right, Cm.	To Left, Cm.	Transverse Diameter, Cm.	Height, Cm.	Oblique Diameter, Cm.	Cardiac Triangle, Sq. Cm.
75 white males	1.92	8.36	10.28	7.89	12.10	34.95
73 white females	1.53	8.01	9.63	7.32	11.49	35.24

In this category of male patients about one-third showed enlargement to the right, figures of 3 c.m. and even 6.5 c.m. being encountered. Quite a number of cases were encountered in which the area of relative cardiac dullness did not extend to the right from the midsternal line. The average figure for the left diameter is only slightly less than in the second stage cases; in forty instances it measured more than the average, maximum values of 15 c.m. being recorded, the minimum being 6.5 c.m. In thirty-four instances the transverse diameter was above the average. The average height is not very different from figures given for the second stage cases; in thirty-four instances higher figures were found even reaching 12.5 c.m. The oblique diameter appears in thirty-four instances above the average, reaching a maximum of 16.2 c.m., a minimum of 9 c.m. The average square surface of the triangular percussion area appears smaller than in the second stage cases; in fifty-seven instances the figure is higher than the average, in one instance the figure amounted to 77 sq. c.m. In nearly 50 per cent. of the cases the size of the heart suggested dilatation.

Among the female white patients classified as third stage cases an enlargement of the cardiac dullness to the right was rarely encountered (only in four instances); more often, however, the borderline was close to the midsternal line, in eight instances it was found very near the left sternal border. In nearly one-half of the patients the left cardiac diameter was increased, seven ranging above 10 c.m., the maximum being 11.3 c.m. In twenty-two instances the transverse diameter was above the calculated average, some of them measured 11.6 and 12.6 c.m. In thirty-four instances the average height was above the quoted figure, amounting to 9 and 10 c.m. The average oblique diameter was exceeded in 19 instances, figures of 14 and 14.7 c.m. being noted. In twenty-eight instances the average square surface of the relative cardiac triangular area exceeded 48 sq. c.m., being the highest values found; twenty-two instances were noticed between 12.9 sq. c.m. and 30 sq. c.m. The percentage of cardiac dilatation appears smaller in the female patients as compared to the male sex; the left, transverse, and oblique diameters are also not so much changed.

Seventy-five White Males.

	Mitral.		Tricuspid.		Aortic.		Pulmonic.	
	I.	II.	I.	II.	I.	II.	I.	II.
Normal	5	67	16	72	66	22	70	15
Indistinct	20	3	20	3	8	25	5	17
Murmurish	9	4	6	..	1	1	..	1
Accentuated	15	4	20	..	..	22	..	11
Splitting, accentuated	3	.	1	..	..	1	..	25
Splitting	8	..	3	.	..	3	..	6
Roughened	13	..	9	..	..	1	..	..
Splitting, murmurish	2	..	..	..	..	..	..	..

Seventy-three White Females.

Normal	3	68	55	67	65	28	70	9
Indistinct	14	5	24	6	8	13	3	4
Murmurish	11	..	4	..	..	..	..	..
Accentuated	28	..	10	.	..	19	..	18
Splitting, accentuated	5	..	3	..	..	9	..	26
Splitting	10	..	6	..	..	4	..	16
Roughened	2	..	4	..	..	..	..	..

The heart sounds are recapitulated in the accompanying table, from which we learn that normal heart sounds are less frequently encountered. Especially affected are the first mitral sounds, showing an indistinct, murmurish, or roughened character, while reduplication is less often encountered. The same qualities may be found for the second mitral sounds, and a similar statement holds also for the first tricuspid sound. In the quality of the first and second aortic sounds not much difference is noticeable, if we compare the results with the same number of second stage cases. As regards the pulmonic sounds indistinct sounds may be slightly more fre-

quent, while instances of splitting and accentuation of the second sounds are increased, as are also the number of cases of indistinct character of the sound. Similar observations were noted in the female patients, accentuation and splitting of the first mitral sound prevailing over the indistinct sound qualities. Indistinct first tricuspid sounds are slightly more frequent than cases of accentuation; accentuation of second aortic sounds is more frequent, and the same is true as regards the second pulmonic sounds.

A few remarks may be added in regard to the pulse, blood pressure, and vasomotor phenomenon. The accompanying table gives the average values of pulse, systolic and diastolic pulse pressures, and cardiac pulsation activity per minute.

tent of the pulmonary involvement. Quite frequently the auscultatory method was not sufficient for the recognition of the weak sounds, and they were not even always obtainable by the palpatory method. Very frequently vasomotor phenomena were existent simultaneously. Dermography, long lasting, and the Ashner bulbus phenomena with slowing and dicrotism of the pulse were occasionally present and attended by collapse of the patient. It must be said that with irregular septic temperature the signs of cardiovascular failure were more marked, while with normal temperature the blood pressure figures were found a little higher.

Quite frequently, notwithstanding prolonged and carefully observed rest, cardiovascular stimulants of all kinds had no immediate nor lasting thera-

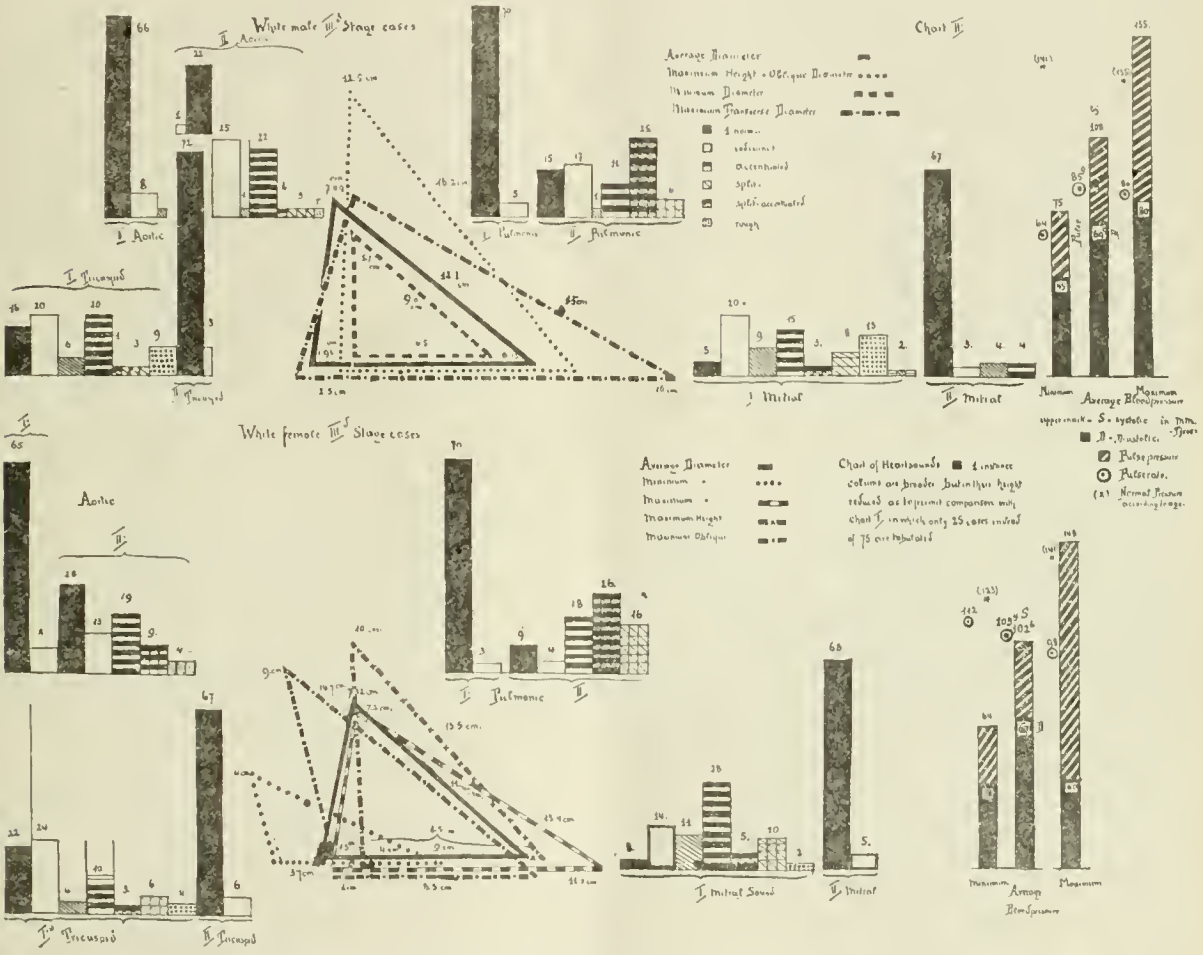

CHART II.—Third-stage cases.

	Pulse.	Systolic, Mm.	Diastolic, Mm.	Pulse Pressure, Mm.	Cardiac Activity, Mm.
25 white males, second stage...	82.3	116 6	75.8	40.8	15,834
25 white females, second stage..	90.5	105.8	72.0	33.8	16,090
75 white males, third stage....	85.9	108 0	69.9	38.1	15,281
73 white females, third stage...	105.4	102.6	67.7	34.9	17,949

If we consider that in most of the cases studied the patients' ages were mostly above 20 years, indeed past 40 years, these figures are very low, and particularly abnormal in consideration of the ex-

peutic result. It is not possible to enter upon a discussion of treatment of such conditions, which constitute a serious handicap in phtisiotherapy. Even if physical signs point toward a quiescent process and the patient may enter the stage of re-education, approaching more normal life conditions, too much exercise without the proper medical control may mean overexertion for the cardiovascular apparatus and lead to undesirable consequences. Although in my experience cardiovascular stimulants in medium and far-advanced cases of pulmonary tuberculosis promise no encouraging results, it is to be hoped that continued research and

better knowledge may open new paths for the improvement of the morbid manifestations which we have discussed.

PRICE'S HILL.

BLOOD TRANSFUSION AS A THERAPEUTIC AID IN SUBACUTE SEPSIS ASSOCIATED WITH WAR INJURIES.

BY ABRAHAM ZINGHER, M.D.,

NEW YORK CITY.

LATE CAPTAIN, MEDICAL CORPS, U. S. ARMY; ASSISTANT DIRECTOR, RESEARCH LABORATORY, DEPARTMENT OF HEALTH.

THIS communication is intended to draw attention to the necessity for the more frequent and extensive use of small and repeated blood transfusions in our military base hospitals. It is only necessary to go through a series of wards containing surgical cases, to realize how beneficial such transfusions would be for these pale, septic looking, and emaciated patients, who are making a difficult uphill struggle to save their limbs or even their lives. The great aid which is so badly needed in the form of a rich supply of red blood cells and blood protein is frequently withheld from these patients, partly by a lack of appreciation of the value of blood transfusion in such cases and partly by an absence of centralized special responsibility for carrying out these transfusions. During the rush period of actual war activities, also, an excessive amount of work for the individual officer and the insufficient surgical help, which existed at times, prevented the systematic and repeated transfusions of blood that were often indicated in suitable cases.

The officers performing blood transfusions also varied in the different Base Hospitals. Sometimes laboratory officers were called upon to do them, at other times a Junior ward surgeon with little or no experience in such work, and again the Chief of the Surgical Service would undertake to do the transfusion himself. The results of such various efforts and the absence of centralized interest in this particular phase of surgery can be seen in the relatively few transfusions that were carried out in some of the hospitals. As these cases often requiring repeated blood transfusions are present now in most of the Base Hospitals and will continue to be present for some time, it is none too late to again call attention to the indications which are very definite in many of the cases. These indications can be summarized as follows:

Indications for blood transfusion. — (1) Extensive suppurating wounds associated with a subacute form of sepsis; (2) compound infected fractures associated with a subacute form of sepis; (3) various grades of anemia dependent upon a subacute form of sepsis; (4) various grades of emaciation and partial marasmus; (5) before and after severe operations as an emergency measure.

While in the forms of acute infections associated with a septicemia blood transfusion has not shown any extraordinary results, in these more subacute forms with a prolonged and extensive suppuration the effects are more likely to be excellent. The freshly injected blood, introduced from time to time, acts in a most beneficial manner in increasing the resisting powers physical, chemical, and immunological, of the patients. Every physician is acquainted with just such cases, in which transfusion of blood has saved lives. But in the saving of limbs, also, a fresh supply of nutritious blood is bound to become an important factor. In these cases the injected blood serves not only to replace the diminished number of red blood cells and the low hemoglobin content, but, as is well known, the injected plasma brings with it an abundance of nutritive and bactericidal properties.

For the anemias the transfusion of blood is certainly indicated. It supplies a fresh amount of blood and also stimulates the patient's blood-forming organs to continue producing an increased number of red blood cells. Yet we see many a patient in our Base Hospitals being allowed to carry on his struggle for recovery without the aid of blood transfusion.

Again, for the cases showing extensive grades of emaciation from various causes such transfusions are definitely indicated. These patients are not only emaciated, but their tissues are more or less devitalized. Such conditions are, of course, generally associated with prolonged sepsis, an inability of the body to utilize the ingested nourishment properly, and with various grades of anemia. They often develop bedsores from pressure upon their bony prominences. These patients have been as a rule lying around in the wards for some time, have gone through many a hard siege with their wounds and do not seem to have sufficient recuperative power to enable them to convalesce properly. Repeated small blood transfusions, by acting as a new stimulant and an important nutritive element, will be certainly beneficial to their undernourished and devitalized tissues.

The cases requiring blood transfusion as an emergency surgical measure are self-evident. Yet lives are sacrificed by a failure to transfuse patients either before or more often after an extensive shock-producing operation. In such cases the injection of blood is a pure life-saving procedure and preparation for it, by previously knowing the blood group of the patient and having on hand a suitable donor, will often mean the difference between saving and losing the patient.

Donors of Blood.—Objections have sometimes been raised that donors are not easily obtainable. Any one who has had experience with blood transfusions knows that donors can be gotten, if any consistent effort is made to get them. With the great desire on part of many civilians to show their patriotic feelings in some direct way that would be beneficial to the soldiers and with the generous spirit of our healthy soldiers, there should be no difficulty in having a classified list of tested donors who could be reached whenever needed. It is necessary, however, that each donor should be, if he so desires, properly remunerated for the blood, which he gives. Relatives of the wounded soldiers in the States are also almost constantly available. It is not, therefore, a question of a lack of donors, but simply that of a lack of appreciation on the part of those responsible for the blood transfusions.

The testing of donors and patients for blood grouping can be readily and conveniently accomplished by the method of Moss, using for the test a serum of Group II and one of Group III. These

test-sera are kept in sealed glass capillaries, so as to have them in convenient form for immediate use. A drop of each of the two sera is placed on a clean glass slide and a drop of blood from the finger of donor or patient is added to each drop of serum. When no agglutination of the red blood cells takes place the individual belongs to Group I; when agglutination with serum of Group III occurs and none with serum of Group II he belongs to Group II; agglutination with serum of Group II and none with serum of Group III indicates that he belongs to Group III; when agglutination occurs with both sera it indicates that the individual being tested belongs to Group IV.

Special Operators in Charge of Blood Transfusions.—The great importance of the subject calls for the assignment of the work connected with blood transfusions to specially qualified officers. It would be very desirable that such an officer, fully conversant with the technical details and indications for transfusion, should be available in every Base Hospital and Base Hospital Center. He could be called into consultation on suitable medical and surgical cases, in which a transfusion is indicated. He even could in a general way know most of the very ill cases throughout the wards and help the surgeons in the selection of those suitable for transfusion.

This officer would also look to the constant availability of donors, and he himself or an assistant would test the donors and patients for blood-grouping. These tests should also be extended to the personnel of the hospital, who might at any time become available as donors. Wassermann tests should, of course, also be made and recorded for each donor.

Method and Technique of Blood Transfusion.—It is generally agreed that for nearly all purposes the citrate transfusion is the simplest and best. Some question has been raised whether the injected red blood cells in citrate transfusions continue to live and functionate in the new host or whether they soon disintegrate. If the blood is immediately injected after it is withdrawn from the donor and citrated, the red blood cells continue, no doubt, to functionate as a part of the circulating blood of the new host. The same holds true for the blood plasma. It is only if the blood is kept as an available supply in the ice-box for days, as is occasionally recommended for emergency purposes, that the red blood cells and the blood plasma are changed and lose most of their value as homologous living tissue. The blood will then not serve the purpose for which it was intended.

The amount of sodium citrate to be used seems to vary with different operators. In the strength of 0.2 per cent of sodium citrate in the final mixture (1 part 2 per cent solution of sodium citrate and 9 parts of blood) the blood will frequently clot at the time of withdrawal and give considerable difficulty at the time of injection. This was the strength originally recommended by Lewisohn. Since an excess of the citrate has been claimed to be toxic, it will be found advisable to use an amount slightly above the one necessary to prevent coagulation and thus obtain a sufficient margin of safety. The writer recommended more than 4 years ago the use of a 0.33 per cent. citrate strength. He adds to each 1.0 c.c. of a 10 per cent. solution of sodium citrate 30.0 c.c. of blood. (MEDICAL RECORD, March 15, 1915.) The greater concentration of the original citrate solution also avoids an unnecessary dilution of the blood to be injected.

The technique of the citrate transfusion has been thoroughly standardized in the Army and it will give as a rule quite satisfactory results. The apparatus which has been devised and is available for use in the Base Hospitals is very good and fulfills all the requirements for convenience and accuracy.

Amount of Blood to be Transfused.—The amount of blood should not be large in the cases considered here, unless we are dealing with a secondary hemorrhage or an intense degree of anemia. Generally from 250 to 300 c.c. of blood will be found sufficient. Such transfusions avoid the danger of suddenly throwing upon the circulation an excessive burden, to which the frequently degenerated heart muscle may not readily adjust itself. The transfusion may have to be repeated several times. It becomes necessary, therefore, to avoid cutting down upon the veins when doing a transfusion. There is, in fact, very seldom any reason for the operator to cut down upon the vein of an adult, except under very unusual circumstances. Very few adults will be found whose veins cannot be made sufficiently prominent by a properly applied tourniquet. One sees from time to time patients coming to Base Hospitals, who show ugly scars at the bend of the elbow following exposure of the vein for purposes of blood transfusion. Unless these operations were carried out as an extreme emergency, they seem to be rather unjustifiable.

Repetition of Blood Transfusion.—This would depend to a large extent upon the special indications in each case. The progress of the wound, the hemoglobin content, and especially the general condition of the patient are good criteria to go by. The intervals between the transfusions would ordinarily be from 7 to 14 days. One important factor, which is not always considered, should be borne in mind. The blood, namely, of one donor may be much more suitable for a patient than that of another one. For that reason, also, the transfusion should be repeated, with the blood from another donor, if the progress of the patient is not as satisfactory as could be desired after one transfusion.

Studies of the Effects of the Blood Transfusions.—Special studies should be made and careful records kept of the effects of single and repeated blood transfusions in these cases of subacute sepsis associated with war wounds and infected compound fractures of the limbs. The tabulated reports from the different Base Hospitals in these groups of cases would soon offer valuable data by which to gauge the exact value of the limb and life-saving effects of such transfusions.

Summary and Conclusions.—1. Blood transfusions should be used more extensively on the wounded soldiers in the base hospitals.

2. Officers should be especially assigned to this work in the different Base Hospitals and Base Hospital Centers, whose sole duties would be in connection with the performing of transfusions, consultations on surgical and medical cases, and the keeping suitable donors available.

3. The special indications considered here are subacute sepsis, associated with extensive suppuration or with infected compound fractures, with anemia

and emaciation of varying grades; also as a prophylactic measure in enfeebled individuals before severe operations and in cases of post-operative surgical shock resulting from extensive loss of blood during an operation.

4. Large pockets of pus, suppurating joints, or extensive empyemas must, of course, be freely incised and drained. No blood transfusion will help in the elimination of these sources of continuous reinfection, unless they are carefully watched for and taken care of as they arise. Autopsies often bring to light such complications, which should have been taken care of while the individual was still alive.

5. The transfusion should be of moderate amounts of blood, from 250 to 300 c.c., and repeated, if necessary, every 7 to 14 days.

6. Systematic efforts should be made to find these patients in the Base Hospitals. Special studies should be made and careful records kept after the transfusions, so as to obtain as soon as possible tabulated data that will help in more definitely indicating the value of blood transfusion in these cases of subacute sepsis associated with extensive wounds and fractures.

A RETURNED SOLDIER CARRIER OF MENINGOCOCCUS.

By CHARLES HALPIN NAMMACK, M.D.

NEW YORK.

PATHOLOGIST, BUREAU OF LABORATORIES, DEPARTMENT OF HEALTH, NEW YORK CITY; ASSISTANT VISITING PHYSICIAN, BELLEVUE HOSPITAL; INSTRUCTOR IN CLINICAL MEDECINE, CORNELL UNIVERSITY MEDICAL COLLEGE.

THE soldiers returning from Overseas or Home Military Service do not, as a rule, constitute a prolific source of disease to the civilian population with which they are again merged. This is due to the careful final examinations which are made by the Army Medical authorities prior to embarkation abroad and to discharge on this side. There may, however, be an exception in epidemic cerebrospinal meningitis of which the following case furnishes an example:

The father of the patient was a private in the Fifty-second Infantry, A. E. F. On November 20, 1918, he was admitted to the Base Hospital at Allerey, France, suffering from dystentery. On December 8 the patient in the bed next to him developed meningococcus meningitis. Of the sixty-five patients in the ward, he and two other men were found to be carriers—as their nasopharyngeal cultures were positive for the meningococcus. N ofurther cases developed. The three carriers were confined in an isolation ward with appropriate treatment until December 25, 1918, when, after three negative cultures from the nose and throat, they were discharged. He returned to his command January 12, 1919. Since then, so far as he knows, no case of meningitis has occurred among the men with whom he has been in contact.

On June 5 he sailed for the United States, arriving at New York June 12. He was discharged from the army and rejoined his family, consisting of his wife and six-months-old daughter, on June 17. On June 22, while at Poughkeepsie, N. Y., his baby, the patient, developed symptoms of meningitis, a diagnosis which was confirmed by lumbar puncture at that place. There was no history of other exposure to the disease.

The patient was first seen on June 25, 1919, presenting the clinical picture of meningitis. Meningococci were abundantly present in the smear from the spinal fluid and were proven culturally. Five lumbar punctures were performed and four doses of Department of Health antimeningitis serum were administered intraspinally, with an uneventful and complete recovery.

On June 26, 1919, the patient's father having volunteered the information given above, he was sent to the laboratory, where nasopharyngeal cultures on vitamine-agar were taken by Miss Helen Hussey, and the meningococcus was found and identified in pure culture. Treatment was instituted, consisting of frequent gargling of the throat with Dobell's solution and the instillation of a few drops of 20 per cent. argyrol in each nostril threetimes a day. After this treatment, cultures were taken on July 2, 8, and 14, which proved negative, and he was discharged. He had cooperated with us very intelligently and cordially, so he was advised to continue the treatment and to report again in a month, after a lapse of treatment for two days, to the laboratory for another culture.

The conclusions, which one reaches as a result of a clinical incident of this kind, present themselves as questions, the answers to which have never been worked out on a very satisfactory basis.

1. It would seem advisable that all service men who have had or been in contact with meningococcus meningitis at any time during their service, be tested for meningococci. This would protect the civilians and would not retard the prompt discharge of the negatives.

2. Might not the incidence of epidemic cerebrospinal meningitis which is endemic to this city at all times be diminished by carfeul examination of all contacts and convalescents and the treatment of all carriers? In the past, there have not been secondary cases in the same block and only rarely in the same family, which has indicated that the patients convelescent from the disease and the contacts have not seemed to be spreading meningitis. It is possible, however, that those in the immediate vicinity were less susceptible than others met outside.

3. Does the carrier constitute a grave menace? Apparently not in civil life, except in time of epidemics. In military life, the carrier is, unquestionably, an important factor.

4. It is evident that the mere finding of three negative cultures does not constitute proof of the continued sterility for meningococcus in a carrier. If practicable, they should be reexamined after an interval and treatment reinstituted if necessary.

I am indebted to Dr. Mary Friedman, 2 West 103d Street, New York City, whose patient this was.

379 PARK AVENUE.

Cause of the Influenza Pandemic.—Silberschmidt, as a result of correlating many finds, eliminates Pfeiffer's bacillus as the cause of the pandemic. He gives the arguments of those who hold the opposed view and accepts then in part but they do not change his conclusions. For example he admits that it is often hard to find and that with patience we may often have to revise our opinion in a given case, but they very seldom occur in massed numbers and they occur early rather than late. He cites the fact that when influenza has not been prevalent he has found the germ in question in fatal meningitis. To assume an unknown virus is no hardship, for we have to do this in measles and scarlet fever, and when these affections threaten and take life it is because of the same secondary exciters as in grippe—pneumostreptococci. The analogy seems complete.—*Correspondenz-Blatt für Schweizer Aerzte.*

Medical and Surgical Lessons of the War.

COMMOTIONAL SHOCK CAUSED BY SHELL EXPLOSIONS.

FOCAL LESIONS PRODUCED BY CONCUSSION; THE COMMOTIONAL AND THE EMOTIONAL SYNDROMES.

By DR. ANDRÉ LÉRI,

PARIS, FRANCE.

PROFESSEUR AGRÉGÉ À LA FACULTÉ DE MÉDICINE; PHYSICIAN TO THE HOSPITALS.

AMONG the most curious and the most unexpected medical facts which the war has revealed to us, we must place in the front rank that of concussion from shell explosions.

Before the World War we would never have supposed that the compression of the air produced by the explosion of a projectile could be so great that this compressed air could act as a solid body and shake and dislocate, so to speak, the nervous centers, causing hemorrhage there, and sometimes sudden death, without the occurrence of any direct blow to the cranium or the spinal column by a shell fragment, stones, clumps of earth, or débris of any sort. Thus the first men brought to us complaining of persistent nervous troubles, in particular mental and physical asthenia, alleged more or less authentically to have followed the explosion of a shell, were received with a certain degree of incredulity; most of us regarded them as neuropaths, more or less conscious or unconscious hysterics, and often not far removed from exaggerators, perseverators, or malingerers.

From the beginning of hostilities, however, there was observed a series of very surprising phenomena which we were forced to attribute to nervous commotion. It was repeatedly stated that soldiers who had been in close proximity to an exploding shell died instantaneously, without a single motion, even keeping the very position in which they were at the time. Men of authority and worthy of credence affirmed that they had seen cases of this sort, and they attributed the fatalities to massive poisoning by the gases of combustion; but this was never established scientifically. The fact is that cases of this kind disappeared almost entirely after a few months, at exactly the time when the small caliber shells, which were the only kind used in the beginning, began gradually to be displaced by shells of larger and larger size. Now if these were really cases of enormous concussion or of massive intoxication, they should have multiplied precisely at this time; but in fact this was the moment when they disappeared from observation. This was the period when the war was, so to speak, organized, in respect to the medicochirurgical service as well as to every other. We were now no longer content with observations made on the fly and passed along from mouth to mouth; the cases were examined more carefully and often there were found wounds of the cranium, which, however small and hidden, were nevertheless amply sufficient to have caused death.

I have myself seen a case of this sort. The presence of the Babinski sign on one side alone prevented me from putting down as a pure neuropath or a malingerer a man who was brought to us with symptoms of a mild torpor alternating with a strong disposition to joviality and humor. The Babinski sign led us to the discovery of a minute and already cicatrized wound of the scalp on the same side as the toe phenomenon. This minute wound had, however, been the portal of entry of a projectile which had passed from one side to the other through both hemispheres. The patient died soon after from a meningoencephalitis.

Thus the legend of innumerable sudden deaths from the explosion of shells of small caliber (of the 75's in particular) have gone to join in oblivion all the many other fables created by popular imagination at the beginning of this war, as well as all periods of great disturbance in history.

Infinitely more important, because eminently scientific, statements were made by Leclerc and by Sencert early in 1915. These authors reported finding hemorrhages in the viscera of subjects dead of traumatic shock after the explosion of a shell in close proximity, without any external wound and without having been touched by the projectile.

Ravout reported soon after this a case of bloody cerebrospinal fluid in a subject in whom paraplegia had occurred under the same condition—explosion of a shell close at hand, but without any sign of a wound or contusion. Similar facts were later noted by Guillais, Heitz, sonques, André Léri, and others. In most of these cases, however, we could not affirm that the patient had not received a blow, if not by shell fragments, at least by stones, clods of earth, or other débris, or that he had not fallen on the back or on the head. Now in a number of cases it has been shown that a blow of this kind may be sufficient to cause hemorrhage in the nervous centers. For example, in a case cited by Porot, a young person without any tendency to hemorrhages and with no signs of vascular disease had suffered from an extensive hematomyelia caused by a simple fall on the back without any signs of injury on the body. Certain facts, however, noted especially by Guillais and by myself, are not open to this objection; the *near-by explosion alone* had been capable of causing hemorrhage in the nervous centers.

These facts attracted great attention, even too great, one might say, for they excited too strong a reaction and they had a tendency, contrary to what had prevailed up to that time, to lead one to regard the nervous troubles consecutive to a more or less violent shell explosion as entirely due to actual commotion or concussion, that is to say, as being associated with organic lesions. Under the term "commotion" in France, or of "shell-shock" in England and America, were included all the nervous troubles following an explosion, without one taking the trouble to determine whether they were of functional or organic origin. As certain clinical facts had shown the possibility of organic lesions, as certain animal experiments had shown also the possibility of cerebral nerve lesions following explosions, it was said that one should be cautious regarding nervous troubles following the explosion of a shell, and that since in law the accused has the benefit of the doubt so in war medicine the "commotionné" should benefit by the doubt.

This very simple conception might well entrain deplorable consequences, at least for the State treasury, for if it is true that at first we had refused too absolutely to accept as reason for sick leave the organic consequences of explosives, soon sick leaves were granted wholesale to all who had the word "commotion" on their evacuation cards. Now, this word was the most vague of all generic terms; it could be applied, so to speak, to all those who had been evacuated from the front, even those who had evacuated themselves without being wounded. Among these were those who were sincere and those who were not sincere; and even among the most honest, every soldier at the front having seen shells fall more or less close to him, there were very many whose troubles were certainly unrelated in any way to the fall of a shell. And, further, even among those in whom the explosion had indubitably caused nervous troubles, there were many in whom a single examination by a physician of experience in most cases could have made it clear that we had to do with purely hysterical troubles, easily recognizable and easily curable. And, finally, among the remaining non-hysterical cases there were still many suffering from the consequences of an emotion, some of a contusion, but relatively few of a real commotion or concussion with organic basis. Now, these different disorders have consequences of very unequal gravity.

One can realize the necessity of distinguishing these different troubles one from the other, instead of giving them a value proportioned rather to the noisy character of the symptoms than to their real importance, when I say that among those who have actually suffered from a shell explosion, 5 per cent. at the most suffer from commotion, and about 95 per cent. from simple emotion. Among the sufferers from true commotion there are very few whose organic lesions are discoverable by an examination of the cerebrospinal fluid or by objective signs of focal lesions; but those suffering from real commotion differ so greatly in their clinical symptoms from the subjects of simple emotion that it is curious that a clear distinction between these two entities was not established from the very beginning. This distinction was all the more easy since it would have sufficed to read again in the older books the too soon forgotten description of cerebral or cerebrospinal concussion consecutive, for example, to a fall on the head or on the back; the description of concussion from a shell explosion almost exactly corresponds to that, but curiously enough, "commotion," a term employed so without measure during the war, had almost completely disappeared, as applicable to a morbid entity, from all the classical treaties.

It is true that the distinction between the subjects of commotional and those of emotional shock called for a somewhat expert examination, but the number of competent neurologists in the army was rather limited, and these were not found, as a rule, in the relief stations or the first line hospitals where the subjects were carried, and if they had been there they would certainly not have had the time to make a careful examination in the hurry and confusion of the attack and in the advanced positions, often underground, where there was hardly room for the seriously wounded and those not able to be transported. Later, when once the diagnosis of "commotion" had been hastily made under these wretched conditions, it was so easy to keep this term, of such wide and vague significance, which did away with the necessity of any very profound study of the case, and which seemed to rest upon the results of the first examination, presumably better because it had been made nearest to the receipt of the causal injury! It is true, also, that in proportion as they became more distant from the causal accident the symptoms of the true conditions tended to approach each other, to mix, and to be more or less confounded, so that the patients of these two groups, on arriving at the interior, far from the front, were hardly distinguishable. The commotional troubles became less distinct, but the emotion, if it was not evident immediately, was at least and forcibly retrospective; a soldier, however courageous he may be, who finds himself, for example, caught in a barrage and then suddenly without any pain finds himself in an ambulance or hospital bed, without any notion of what has happened in the meanwhile, but with only the very clear notion that he has just escaped death almost miraculously, can hardly help having "emotional" symptoms. On the other hand, a violent emotion causes vasomotor and secretory troubles, of a nervous and circulatory character, which are indisputable but which, independently even of any hysterical phenomena, may have very late sequelæ, under the form especially of physical and mental asthenia and of depressive emotivity, which differ very little from the signs of prolonged cerebrospinal concussion. One can then understand that a delayed examination, made far from the front and a long time after the accident, will be surrounded by many perplexities and that, under those conditions, the differential diagnosis may be very difficult. It was, however, then that these subjects were examined most often, for it was in the interior that the physicians had more time to make these rather delicate examinations, and it is no doubt for that reason that most of their descriptions present a very great confusion.

It is near the front, the nearest possible after the accident, that these soldiers should be examined; there, without any doubt, the clinical pictures are essentially different, and if later one follows up the patients, it is still by their differences that they strike the expert physician. But, on the other hand, it is the resemblances which will dominate the clinical picture if the physician is ignorant of the early stages of the true circumstances of the accident itself.

Having had the good fortune to direct for several years the neurological center of the army which was perhaps the most active of all, namely the army of Verdun, I was able to examine near the front, almost immediately after the accident, a great number of those suffering from commotional and from emotional shock, and was thus able to understand how important it was to distinguish one from the other those innumerable "wounded without wounds," in order to give to each not only the immediate treatment indicated, but also for the future the more or less prolonged or definitive rest, and the bonus proportioned to the gravity of their organic lesions or to the degree of their real incapacity for work. To this end I studied without

prejudice the physical and mental state of the patients; and the precise knowledge of the place and circumstances of the accident, which one could gain only at the front, was most valuable. We were thus able to classify those patients simply and naturally, and then compared them with those we had seen in the interior far from the front, who, for us, as well as for so many others, had constituted up to that time a thick mass of clinical pictures quite indistinct, complex and almost inseparable, except arbitrarily and artificially, so greatly did their manifold symptoms overlap each other.

In this article we shall note first the chief cerebral or spinal focal lesions following shell explosions, emphasizing certain cases in which the relation of cause and effect between the lesion and the explosion alone was indisputable, and we shall also call attention to certain cases in which the clinical evolution was especially remarkable and the clinical picture unexpected. We shall then show how, except for the cases, which are moreover rare, of focal lesions, it is easy to distinguish from the beginning the subjects of commotion from those of emotion (and also of cerebral contusion), how the clinical pictures later became confused and complicated, although preserving a certain individuality, still recognizable by the expert clinician, who is conscientiously anxious to arrive at just medicomilitary decisions, not only during the war but also in the post-bellum period.

Focal Lesions of the Nervous Centers from Shell Commotion

Focal lesions following explosions have been noted in the spinal cord and in the brain.

Spinal cord lesions have been reported by Ravaut, Guillais, Heitz, Froment, Pierre Marie and Chatelin, Ballet, Joubert, Souques, André Léi, and others. They are almost always manifested by paraplegia. The indisputably organic nature of these paralyses has been established in most cases by the clinical examination only. The symptomatology of certain of these cases enabled a diagnosis to be made not only of an indefinite spinal cord lesion, but of hematomyelia (cases of Heitz, P. Marie and Chatelin, Ballet and André Léri). In some of the observations a lumbar puncture gave exit to a distinctly bloody liquid (Ravaut, Joubert), and sometimes it was this blood-stained liquid which revealed the organic nature of the troubles noted.

In a general way the spinal cord lesions have been often more demonstrative than the cerebral ones, because, although there was almost always a fall, in many cases, at least, the patient did not lose consciousness and was able to affirm that it was not the fall that caused the lesion, but the paraplegia which determined the fall. In some rare cases even there was no fall; either the patient was lying down (Froment's case) or the paraplegia did not occur at once and the patient had at least time enough to sit down (case of P. Marie and Chatelin, of Souques and of André Léri).

Cerebral lesions following shell explosions have been reported by various writers; they were manifested for the most part by hemiplegia (cases of Guillais, Ravaut, Souques, Mézevaud and Donnet, Henri Français, Babonneix and David, André Léi, and others); sometimes aphasic troubles were noted, either associated with hemiplegia or alone (case of Pierre Marie and Jules Lévy, Souques, Claude, Pierre Marie and Foix, and André Léri).

In almost all the cases the soldier lost consciousness and fell, so that there was always a doubt regarding the rôle of the fall and of a consequent blow on the head in the production of the cerebral lesions. We have knowledge of only two cases reported by Guillais and of two coming under our own observation in which the cerebral lesions were produced without loss of consciousness and in which there was neither a fall nor a blow of any sort caused by even slight traumatisms which, although apparently accessory, one could not have helped an inclination to incriminate, especially if they were caused by the shell explosion. In these cases we could feel certain that the nearby explosion was really the only cause of the cerebral commotion and lesions.

One of our patients, a young man of 20 years, hearing a large shell coming, lay on the ground; the shell exploded at a distance of 2 or 3 yards to the left of him; he was not touched by any shell fragments, pebbles or clods of earth. He rose immediately, stunned, and with pain on the right side of his head. He went down into a dugout for ten minutes and then went off to a field some 200 yards away to play ball. He played for about half an hour, but during the game noticed that his bat frequently dropped from his left hand for the reason that he could not feel it; he also stumbled and fell several times because he could not tell in what position his left foot was. He returned to the dugout, lay down for a while, and then started to get up but fell, the left side being completely paralyzed, and almost immediately lost consciousness. He was evacuated, and a lumbar puncture made that same evening gave exit to a fluid deeply blood-stained. Examination showed a left hemiplegia, rapidly becoming spasmodic, almost complete and total, with exaggeration of the tendon reflexes and the extension toe reflex, and with abolition of both superficial and deep sensibility on the left side.

The troubles bore thus an evident relation to the commotion caused by the shell explosion alone; they were rapidly progressive, beginning with sensory disorder, the motor tracts being involved later. The lesion could therefore be localized primarily in the optic layer, and the hemorrhage, the occurrence of which was positively shown by the cerebrospinal fluid, involved the internal capsule and the ventricles.

Another of our patients, an officer 45 years old, was making a reconnaissance in a trench when two shells fell on the parapet, one at the right and the other at the left. He fell on his left arm but immediately rose without assistance, and his head did not touch the ground, as was asserted by himself and confirmed by the two officers who accompanied him. He was taken to the post of the command, distant about 30 yards, being supported under the arms. He had no paralysis of the extremities, but suffered from a pure motor aphasia, clear and well defined, which only a very superficial examination could have mistaken for hysterical mutism, the circumstances of the accident being taken into consideration. A few days later he had an attack of Jacksonian epilepsy, localized in the right shoulder

and arm, and accompanied by a serious syncopal state, which would have confirmed, had this been necessary, the organic nature of the brain lesions. These lesions were produced without any fall on the head or blow by shell fragments or débris of any sort; the shell explosions supplied the only possible cause.

Mesencephalic lesions were relatively frequent following shell explosions; Guillais, Rist, Henri Français, and Pitres and Marchand have noted cerebellar syndromes occurring under these conditions. I myself have seen one case in which, following an explosion, there were complex organic troubles explicable only by the presence of two lesions at least in the bulboprotuberantial region, one involving the bulbocervical centers on the left side of the spinal accessory, the hypoglossal and the brachial plexus, the other wounding on the right side the bulboprotuberantial trunks of the trigeminus and the external motor oculi.

Another of our cases was remarkable by reason of the considerable extent of a bulbocervical hemorrhage which had determined at once a typical Millard-Gubler syndrome—paralysis of the face on the right side and of the extremities on the left, with very pronounced disturbances of speech, of mastication, and of deglutition. This patient, examined late, presented as a remainder or sequel of his lesions a very complex syndrome, comprising (1) an atrophic paralysis, bilateral but most marked on the right, of the face, the lips, the masseters, the tongue, the pharyngeal and laryngeal muscles, the sternomastoids, the trapezius, the sub- and supraspinals, the pectorals, the rhomboids and the diaphragm; (2) marked disorders of taste and loss of hearing on the right side; (3) a great diminution of all sensibility in the domain of the second cervical on the right; (4) a slight atrophy of the hands of the Aran-Duchenne type and a marked dissociation of sensibility of syringomyelic type in the hands and forearms. These symptoms indicated that the lesion involved: in the bulb, the origins of all the cranial nerves from the V to the XII pairs; in the superior cervical region, the three or four first spinal segments.

What was still more remarkable was that notwithstanding the extent of the hemorrhage in the bulb this patient recovered sufficiently to be sent back to the front, and when he again saw the shells falling, unconsciously imitating the speech disturbances of bulbar origin from which he had suffered, he had an attack of hysterical mutism for which he was returned to us.

In the very great majority of cases the commotional lesions show themselves immediately after the bursting of the shell, whether the man has fallen or not, and whether there is paraplegia, hemiplegia, aphasia, or what not. But in some cases we have seen "tardy" symptoms, these coming on gradually, hours, days, or even weeks after the explosion. We have already mentioned a case in which a purely commotional hemorrhage of the optic layer revealed itself only little by little in the succeeding half hour. A patient of Froment's, who was lying down, rose and walked with help for a quarter of an hour before complete paraplegia declared itself. A patient whose case was described by Pierre Marie and Chatelin walked for nearly two hours after the explosion, complaining of increasing fatigue and heaviness in the right leg; then he lay down and slept, and it was not until the following morning that he found he could not use his right leg or rise. In these cases there was no actual "period of meditation" between the explosion and the appearance of the first symptoms; these were immediate, but they became complete only after a certain lapse of time, keeping pace, no doubt, with the progressive extension of the hemorrhage.

In the following cases there was, on the contrary, a long and more or less completely "mute" period which followed the explosion, at the expiration of which the first gross organic eruptions appeared, which, however, bore an evident relation of effect from cause with the explosion. These "tardy" commotions seem to me worthy of notice, given their importance from the point of view of questions bearing upon medicomilitary decisions which may be raised long after the war, and since an ignorance of them might prevent recognition of a relation of cause to effect, often unexpected but often also indisputable.

Thus one of our patients saw a shell of medium caliber explode three or four yards away; he was raised off the ground but fell on his feet; he did not lose consciousness and felt no blow, nor did he show any contusion. He was greatly fatigued, but kept on his feet and walked to the cantonment, a distance of about a kilometer (five-eighths of a mile). The next day he had diarrhea and the day after he was evacuated with a diagnosis of "dysentery." He continued to walk well and could move all four limbs perfectly. He passed the night at the evacuation hospital, and it was while there that, on waking, *three days after the explosion,* he found he was completely paralyzed in the left arm and leg. The hemiplegia was distinctly organic, with exaggeration of the tendon reflexes, foot clonus, Babinski sign, etc. The man was young, with no syphilitic, malarial, or cardiac trouble, and nothing other than the commotion following the shell explosion seemed capable of explaining the cerebral lesion whose delayed manifestation had appeared three days after the accident.

Another subject, very energetic, young, and without any pathological antecedents, after the explosion quite near him of a shell of large caliber, felt extreme fatigue which kept him from sitting down during the entire day, because he had the impression that he would not be able to rise again if he did. It was not until several days later, however, that the signs of organic paraplegia appeared, and, several weeks after this, symptoms of hemiplegia, both, however, happily disappearing eventually almost completely.

A soldier, 21 years old, was suddenly startled by the explosion of a torpedo very close to him; he continued in service without experiencing any trouble, and it was not until the following evening, while on guard duty, that he presented suddenly a series of cerebellar symptoms; he lost consciousness, and examination revealed a pure cerebellar hemiplegia due to a lesion of the superior cerebellar peduncle. Among the antecedents we could learn only of typhoid fever three weeks before, which had perhaps predisposed the vessels to rupture.

Spinal commotions with late manifestations are perhaps more frequent than the cerebral or cerebellar lesions, but they presented themselves to us not under the form of a spasmodic paraplegia with dissociated anesthesia, symptomatic of hematomyelia, but under the unexpected form of a more or less extensive amyotrophy, having the clinical and electrical characters of the myelopathic atrophies, but with an irregular dissociated localization not corresponding to any clinical type of spinal amyotrophy, and with a tardily regressive evolution which is not characteristic of the ordinary spinal amyotrophies, almost always progressive.

The first patient whom I saw with Froment and Mahan had a very large shell fall at three or four yards from him, but he was not touched by any fragment. During the two following days he accompanied his comrades during short marches of from one to four kilometers (⅝ to 2½ miles), but with difficulty, and also he found he could no longer buckle his knapsack. The *third day* he marched again, with difficulty, a distance of three kilometers (nearly two miles) to the trench. On arriving there he sat down and then could not rise again, He was evacuated, and that same evening he found himself unable to carry food to his mouth. Thus for two months he was unable to make the slightest movement, except of the head and neck. There were no disturbances of sensation and the sphincters were normal, but a generalized muscular atrophy appeared. When we saw him first he presented a type of advanced myopathy but with, in addition, a marked atrophy of the hands and an incomplete reaction of degeneration in certain muscles. In the course of time the atrophy gradually disappeared, though incompletely.

Another soldier was in a trench when a shell of medium caliber (105 or 120) exploded on the parapet about a yard in front of him; he was sitting down and was buried up to the waist, but felt no injury and continued in service. The following day he felt quite fatigued and was given a post of relative quiet. He froze his feet and was evacuated for this reason *five days after the accident.* He experienced his first symptoms during the evacuation journey, being unable to unbutton his trousers, to enter the train without assistance, or to write a postal card. He was put to bed, and on trying to rise he fell over. He arrived at his destination paralyzed in all four extremities, with a slight elevation of temperature, but without pain and with no anesthesia. By the fifteenth day after the accident he noted a certain degree of atrophy of the four extremities; the atrophy increased until, a year later, upon examination at a neurological center, there was found "generalized muscular atrophy in all the muscles of the body except those of the head, but without any disturbance in the electrical reactions or modifications of sensibility." Six months after this we found only a slight degree of atrophy of the upper limbs, and especially of their extremities (dorsal surface of the forearms, interossei, hypothenar eminences, and inner portion of the thenar), simulating more or less a bilateral atrophic paresis of the ulnar; there were no reflex or sensory disturbances.

In the two preceding observations, remarkably alike, the relation of cause to effect appeared to be very evident in the explosion of the shell and the amyotrophic paralysis in tetraplegic forms; but the nature of the lesion is very problematical. In the following case the relation of cause to effect was, on the contrary, less evident at first sight, because the period of "meditation" was longer, but the mode of onset makes us think more of a hematomyelia. It is thus that these different observations, when compared, seem to elucidate each other.

A soldier, 28 years old, was at the door of a shelter when a shell, probably of 150 caliber, fell on the shelter and destroyed it, the soldier being, as it were, dragged back and thrown to the bottom of the shelter. He lost consciousness, and when he was dug out from under the rubbish ten minutes later his mouth was filled with dirt; he came to himself shortly after, and after rinsing out his mouth at the door of the first-aid station went back to his place and resumed his guard duty. Several days later he had a quite severe sore throat, on account of which he was evacuated. Three or four weeks after this explosion one morning on rising he suddenly felt his lower extremities stiff and unable to sustain him, and was obliged to lie down again. For a month his legs were rigid and inert, even when in bed, and they were still a little stiff when he got up; later they became soft and flaccid and gave way under him. About six months later, after several transfers from one place to another, he underwent a two months' course of treatment at the Salpêtrière in the service of Professor Pierre Marie. He was there reported to have a total loss of sensibility, and his certificate bore the diagnosis: "Generalized muscular atrophy, lumbar myelopathic syndrome with weakness of the legs." At the end of another six weeks we could hardly make out any weakness of the lower extremities, there was no amyotrophy, and no disorder of the reflexes or of sensation.

Other observations do not differ from the preceding except in the following points: the localization of the amyotrophy, always irregular, corresponding to no radicular or peripheral distribution, was more or less diffuse or disseminated; the onset, sometimes rapid as in the cases above related, was at other times slowly progressive; the period of "meditation" was more or less prolonged; the commotion seemed sometimes to be very slight, so slight, indeed, that the patient himself attached but little importance to it, and it was necessary to make an intentional search in order to find a cause for the wholly abnormal and atypical clinical picture.

It is precisely because it is necessary at times to search for the causal commotion with deliberation and intention, although in the immense majority of cases this forces itself into the mind in an excessive and too exclusive fashion, that we have felt it necessary to insist upon these "retarded" commotions which are little known, especially under the curious amyotrophic form to which attention has been so little called hitherto. These retarded commotions are in fact the ones which call later, after the war's end, for some very delicate medicomilitary decisions. Up to the present there has been a great tendency to deny any relation of cause and effect between the accident and the lesion when a cerebral or spinal lesion has appeared some days, weeks, or even months after a shell explosion.

The facts which we have observed, and which are, so to say, graded, force us to admit that such a relation of casualty does in fact exist. It is further to be remarked, and this is important from the point of view of the decisions to be taken, that the prognosis of the retarded lesions seems usually to be infinitely better than that of immediate or precocious commotional lesions.

With the question of retarded commotion ought to be considered that of *post-commotional epilepsy.* The epilepsy may indeed be the almost immediate consequence of the explosion of a shell. Guillais has observed two cases of generalized epilepsy occurring under these conditions, and we also have seen a case of Jacksonian epilepsy so occasioned. The patient was an artilleryman, the head of whose horse was carried off by a shell coming from the left; the man fell on his left hand, but *his head did not strike the ground.* During the night, two hours after the accident, he suffered from his first attack of Jacksonian epilepsy, starting on the right side; the second attack did not occur until some months later, then two attacks in the course of one month. These attacks, medically studied, were unquestionably epileptic.

Instances of this kind are, however, rare. In the great majority of cases it is not a cortical or subcortical hemorrhage which causes the epilepsy; it is rather the sclerosis resulting from the cicatrization of the focal lesion. Therefore, as a rule, the epilepsy declares itself tardily, *several months after the commotion,* and the relation of cause and effect, which is so important, becomes then very problematical. One thing is certain, and that is that we have seen an increase in the number of cases of epilepsy since the beginning of the war. Has the disease in these cases been created by the incidents of the war; or have the larval epilepsies been accentuated and brought into evidence by the war; or finally, given especially the youth of a large number of the soldiers, might these cases of epilepsy have occurred even without the fatigues, the emotions and the commotions of the war? It is probable that all these varieties of causation have been in action; a very searching examination of each particular case might throw some light on this, but very often a doubt will still remain. But, however this may be, another observation has struck us, namely, a distinct and often considerable increase in the number of attacks in persons already recognized as epileptic; a certain person, for example, who in the calm of ordinary existence had an attack only every three or four months, will sometimes have them almost every day in the agitated life a tthe front.

In this rapid review of the focal lesions of the sketched only a few of the clinical facts which are liable to create the most interesting and difficult practical problems—especially in the after-war period.*

*We cannot here enter upon a discussion of certain theoretical points regarding the pathology of these commotional focal lesions—gaseous shock, decompression, bulbar shock from impact of the cerebrospinal fluid, etc. These discussions and a number of others will be found in our work entitled "Commotions et Emotions de Guerre," Masson, publisher, an English translation of which will appear shortly.

(*To be concluded.*)

Medicolegal Notes.

Malpractice—No Cause of Action.—In an action for surgical malpractice it appeared that in February, 1916, the plaintiff was in a hospital in care of the defendant as a surgeon for a period of five days. He performed a surgical operation upon her, consisting of the lancing of a urethral abscess. It was located upon the urethra and upon the vaginal wall. At the time of the operation the defendant used a piece of cheesecloth or surgeon's gauze for the purpose of absorbing blood and pus from the incision. This was placed as a packing within the vagina. The particular piece used by the defendant was described by the plaintiff's husband as a witness as being 2 feet long and 2½ inches wide. Ten weeks after the discharge of the plaintiff from the hospital she discovered a smaller piece of cloth or gauze within the vagina, and removed it. The ultimate complaint of her pleading was that the defendant failed to advise her that he had inserted any cloth or gauze in the vagina, and that she was thereby prevented from discovering its presence, and that its long continuance therein resulted in injury to her. The plaintiff's experts testified that the use of gauze or cloth was proper, and that its long continuance without change was not necessarily injurious, though very offensive. The plaintiff was discharged within five days, and her care by the defendant then ceased. Up to that time the presence of the packing in the vagina was neither injurious to the plaintiff nor wrongful on the part of the defendant. If the plaintiff did not know of its presence, her husband did. At the expiration of five days the plaintiff left the city, and accepted no further attention from the defendant. It might well be assumed that during her further convalescence she would seek the aid of a local physician. Not only did the husband know of the presence of the packing, but such presence would be readily discoverable by any physician. Its removal called for no surgical skill.

Assuming, for the sake of argument, that the defendant should have warned the plaintiff and should have instructed her as to the removal of the packing, and that he failed in his duty in that respect, the court held that the evidence wholly failed to show that the presence of the packing resulted in any injury to her. At the time of the operation and for some time prior thereto, the plaintiff was suffering from a serious disease. One of the resulting effects of such disease was the abscess for which she obtained surgical relief. The surgical operation was not calculated to check the disease. The defendant did not treat her for such disease. The symptoms suffered by the plaintiff after the surgical operation were of the same kind as those suffered before the operation, though they grew much more severe with the progress of the disease. Two expert witnesses testified on behalf of the plaintiff that the presence of the packing for such inordinate length of time could produce septicemia, especially in view of its contact with a surgical wound. But they testified also that even this was improbable. It appeared affirmatively and without dispute that the surgical wound "healed all right," and that it was involved in no complication whatever. There was no evidence, expert or otherwise, that she had suffered from septicemia. It was held that there was no cause of action and the trial court properly directed a verdict for the defendant.—Studyvin v. Weston, Iowa Supreme Court, 171 N. W. 15.

Validity and Construction of Harrison Narcotic Act.—Reversing a judgment sustaining a demurrer to an indictment for violation of section 2 of the Harrison Narcotic Act (246 Fed. 958), the Supreme Court of the United States holds that the section, aiming to confine, by imposition of penalties, sales of narcotic drugs to registered dealers, to those dispensing them as physicians, and those coming to dealers with legitimate prescriptions of physicians, inserted in an act specifically providing for the raising of revenue by excise tax on such dealers and others named in section 1, has such relation to facilitating the collection of the revenue as to be within the power of Congress under the authority given it by Const. art. 1, § 8, to impose excise taxes, and is not a mere attempt to exercise a power not delegated, the reserved police power of the states.—United States v. Doremus, 39 U. S. Sup. Ct. 214.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

See fourth page following reading matter for Rates of Subscription and Information for Contributors and Subscribers.

New York, October 4, 1919.

A WORD OF THANKS.

THE present issue of the MEDICAL RECORD, dated October 4, appears seven weeks late, owing to a strike of the pressmen. The delay and its cause were announced to our subscribers and advertisers in a letter from the publishers mailed October 3. In this letter it was stated that, in common with one hundred and fifty-one other publications in New York City, the MEDICAL RECORD had temporarily suspended publication. This is the first time in its fifty-three years of existence that this journal has failed to appear on the appointed date, but the demands of the striking employees of the office where it is printed were so manifestly unfair, even being repudiated by their own governing labor organization, that both printers and publishers realized that the issue must be joined to prevent greater trouble in the future. The letter brought so many and such cordial answers, expressing sympathy and promising moral support in the struggle for principle and the sanctity of contracts, as fully to compensate for all the annoyance and inconvenience which the strike caused. As it would be impossible to reply individually to all the writers of these heartening letters, the publishers and editor take this occasion to express their warmest thanks to all of them and to beg them each and individually to accept this as a personal expression of gratitude for their friendly support.

The delayed numbers will be issued now in rapid succession until the regular order is again established, from which we trust we shall not again have to depart for another half century or more.

THE USE OF FREE OMENTAL GRAFTS IN ABDOMINAL SURGERY.

SEVERAL years ago (MEDICAL RECORD, March 25, 1916) we called attention to the value of free omental grafts in covering raw surfaces, in the replacement of lost portions of the peritoneum, in the strengthening of suture lines, in checking hemorrhage from the liver or spleen, and in various other conditions; and we concluded by stating our belief that "more use will be made of this resource as its value is better appreciated." Since that time but few journal articles on this subject have appeared; yet the value of free omental transplants has been recognized by many surgeons, and references to this resource are found in the more important recent books on operative surgery.

When we first called attention to this subject there were, however, a number of questions regarding indications, technique of use, and the ultimate fate of the grafts under varying conditions that remained unsolved. To clarify the subject Carl B. Davis (*Journal of the American Medical Association*, March 3, 1917) carried out a series of experiments on dogs, transplanting omentum in large and small amounts to the stomach, large and small intestine, liver, spleen, kidney, bladder, and various places denuded of peritoneum. It was also transplanted free beneath the skin to determine its ultimate fate when used for plastic purposes. Davis found that the grafts almost always did well wherever placed, becoming firmly adherent and remaining viable. The spleen and liver were entirely cut through or extensive through and through lacerations of these organs were made with a forceps and the edges then united after an intervening free omental graft had been applied. In these cases he found that the almost immediate hemostasis was quite striking and beyond that which might be expected by mechanical means. The liver and spleen with their free grafts were removed weeks or months later and showed complete viability of the tissues. Grafts transplanted beneath the skin maintained the greater portion of their bulk. One objection to the use of free omental grafts in the abdomen he found to be the enormous production of adhesions whenever the free cut edge was exposed; but he stated that this might be avoided in large part by accurately turning under all raw edges, and the same applies to the stump from which the graft is removed.

These experiments cleared up some of the questions, but Davis seems to have done all of his work in an aseptic field; hence still further experiments were necessary to a complete solution of the problems. The records of the experimental work of Finton and Peet (*Surgery, Gynecology, and Obstetrics*, September, 1919), who seem to have covered the ground very thoroughly, furnish the requisite information. In their experiments dogs were used exclusively and all operations were performed under ether anesthesia with strict sterile precautions. How many experiments were made is not stated; but it is evident that the number was very great. Their experiments had the following aims and results: (1) To determine the fate of detached omentum and the proper size and thickness to obtain the best results when placed on uninjured intestine (aseptic conditions). It was found that the grafts survived in practically normal condition when applied under sterile precautions to any abdominal organ. The size of the graft made no difference in its vitality, but the thickness was im-

portant. The thinnest grafts survived best and were the least likely to favor adhesions. (2) To determine if the vascular condition of the graft influenced its vitality. No difference in vitality could be determined between the grafts which were doubly ligated before being cut away from the omentum, thus leaving the vessels full, and those in which the blood escaped from the cut vessels. (3) To determine whether abrasion of the peritoneum was a factor in the survival of the grafts. Irritation of the peritoneal layer is not necessary, as the vitality of the graft was found equally good when the graft was placed upon uninjured peritoneum as when the area was rubbed or scarified. (4) To determine the best method for attaching the grafts. Grafts were sutured to the intestine with fine silks, with plain, iodine, and chromic catgut. Plain fine silk was found to be the preferable suture material, as practically no reaction was noted about the silk, it could be tied in a very small knot and the ends cut short without danger of the knot untying. Plain catgut, size 00, was very good, but acted to a certain extent as an irritant. Iodine and chromic gut were decidedly irritating and favored dense adhesions. Sutures must be placed at least at the four corners of the graft to prevent rolling. Suturing to the mesentery on each side of the intestine was of no advantage; on the contrary, sometimes it seemed to be a disadvantage, as the mesenteric attachment was the only seat of adhesions to the great omentum or to the neighboring mesentery. Numerous sutures were not necessary, just enough to hold the graft in place being preferable. (5) To determine the fate of detached omental grafts under possible septic conditions. In these experiments the intestine was punctured and the wound closed by Lembert sutures, also lateral and end-to-end anastomoses were made and all of the suture lines were covered by free omental grafts. These grafts survived in every instance when infection was kept at the minimum. (6) To determine the ability of the graft to prevent the spread of infection. When used to close small punctures and the cut edges of an anastomosis after a single approximating suture, the graft succeeded in preventing the spread of infection to the general peritoneal cavity; but it acted more as a mechanical patch than as a living tissue, since the graft always showed marked pathological changes, being densely infiltrated and accompanied by the formation of dense adhesions. The authors concluded that the graft was undoubtedly of benefit, since a general peritonitis was prevented; but this action was only temporary and was supplemented rapidly by adhesions to the omentum or to adjacent intestines. (7) To determine a method of preventing adhesions to the graft. In their other experiments in sterile fields, when no special efforts were made to avoid adhesions except by turning under all cut edges when suturing the graft in place, many cases escaped adhesions altogether. In this series the grafts were either coated with vaseline or with paraffin oil, or were washed carefully with warm saline solution after being sutured to the intestine. The omentum was also folded back and away from the grafts, and in some cases the greater portion was removed. No method was found certain in preventing adhesions. Vaseline and paraffin oil increased their number and density; while washing with saline had no apparent effect. (8) To determine what structures are suitable for the application of omental grafts. The authors found that detached omental grafts could be used successfully on any of the abdominal organs and on the parietal peritoneum.

Regarding technique, the authors say that the piece removed should be from the free border of the omentum; that the graft must be thin and spread out carefully over the injured part, the cut edge rolled under and fastened in place by several fine silk sutures; and that in ligating the stump the omentum should not be markedly puckered and the cut edges should be covered. The indications for the use of free omental grafts and the authors' conclusions are as follows: "The use of detached omental grafts is preferable to fixed grafts except in the presence of a general infection. They may be used on any abdominal organ. The indications are to replace lost portions of peritoneum; to strengthen suture lines; to prevent adhesions; to check hemorrhages; to occlude the pylorus; to cover the stump of the cystic duct or Fallopian tubes; and to reinforce the peritoneum in threatened perforations. The technique is simple and may be performed with little trauma and in a minimum period of time. In the absence of infection the thin graft survives at least six months practically unchanged."

In view of the results obtained by Finton and Peet and the added light thrown upon the subject by their thorough and painstaking work, we feel justified in again remarking that more use will be made of this resource as its value is better appreciated.

THE PROVINCE OF PSYCHOTHERAPY.

THAT the mind may dominate the body is one of the oldest concepts to descend to us. We see it realized daily, and the history of religions is filled with it, especially in the martyrdoms which are inseparable from them all. Science did not take it up until 1846, when Braid, of hypnotism memory, published his essay on the power of the mind over the body. A second birth was seen in the monograph of Liébault on the same subject, published in 1866. This author was succeeded in turn by his colleague Bernheim, whose book on suggestive therapeutics appeared in 1884. Any practitioner who had graduated in medicine up to that period knows that nothing remotely suggesting psychotherapy was taught in his day.

Rabinovitch, in the *Revue médicale de la Suisse romande* for August, 1919, covers the subject of the province of psychotherapy, giving full credit to the obscure Nancy school for priority in this field, and justly, because the work of Charcot and of Breuer and Freud was directed to a very limited field, while

the disciples of the Nancy professors placed no limit on the power of suggestion in the relief of disease. Among prominent neurologists to incorporate the idea into their teachings at an early date were Grasset and Dejerine in France, while Morat, the physiologist, expressed his opinion that no organ of the body could escape the influence of the cerebrum.

Walthard, the well-known gynecologist, created somewhat of a sensation by ascribing many gynecological ailments to mental causes and by recommending a psychotherapeutic treatment for the same. Strümpell and Krehl, among distinguished internists, teach that many cardiac troubles are psychically motivated and curable; while the late Ivor Bang believed that the blood picture could be altered by emotional states, and Elliot has recently traced blood states to emotional influences and mental shock. In these cases it is not a matter of theorizing, but of fact, for Bang has averted these blood alterations by anesthesia of a special type. Dide and Witry have individually shown the psychogenic motivation and curability of certain acute edemas. In 1910 Vogt was able to produce pemphigus blebs by suggestion. The inevitable result of these documents is that it becomes increasingly hard for any advocate of rational therapeutic procedures to exclude the possibility of suggestion.

PROBLEMS OF INFLUENZA.

INFLUENZA is the most epidemic of all affections, and in the absence of epidemicity the diagnosis is impossible, especially if we bear in mind that the presence of Pfeiffer's or any other germ is insufficient for its identification. Since the genuine disease, in distinction from the recurring endemic winter grippe, appears at long-spaced intervals, the great question arises, what becomes of the *materies morbi* during these periods of quiescence? This leads to another question: what serves to rouse it to virulence again?

Professor Sobernheim of Berne, who asks these queries in the *Correspondenz-Blatt für Schweizer Aerzte* for August 21, attempts to answer them as follows: One may assume that the malady persists in a mild or latent form in any community which it has once visited, or may take the opposite view, that the disease has a special home in some one or more places on the earth from which it may become rapidly diffused throughout the world. In other words, it may be autochthonous or exotic and imported. According to the first view the public obtains an immunity from one pandemic which wears off in time and makes possible the second pandemic, and so on indefinitely. This view is plausible in some respects, but breaks down completely when we study the progress of the pandemic throughout the world, and we are forced to assume the second hypothesis, that true influenza is always diffused from a parent focus and has nothing in common with endemic grippe-like affections of cold weather.

The question now propounds itself as to the locality of the cradle of the pandemic. In 1889 the infection was traced back to Turkestan, but in the recent outbreak the scent is lost in Spain—or perhaps in America in the spring of 1918? We do not have to believe that the parent focus is always the same nor is it true that true influenza is perennial in Turkestan or any other country. Figures are very deceptive, as shown by the deaths in Switzerland during 1889-1894. During the pandemic year the deaths were 2959 from the disease, while in 1891 they had fallen to 268. But in 1892 the number was 617; in 1893, 1,376, and in 1894, 2,275. In other words, the virulence of the pandemic was low and but few deaths occurred in its wake. On the other hand, the endemic winter grippe was unusually severe for the next three seasons. If we assume that Pfeiffer's bacillus was the cause of the older pandemic the duration of the latter would have to be reckoned in Switzerland as five years. The persistence of influenza in the wake of a pandemic is one of the great puzzles of the disease however we choose to explain it, and in the older episode there is no suggestion of successive waves of contagion 2 or 3 months apart, as in the pandemic of 1918-19.

THE ALCOHOL-SYPHILIS ASSOCIATION.

THIS subject has a very small literature and most of it lies concealed in articles on syphilis maligna. It is well known that despite the malignant course of syphilis in many alcoholics, others of the latter drink through a lifetime with complete immunity to recurrence of syphilitic manifestations. This fact has been brought in some vague relationship with the negative Wassermann in some of these cases. There are individual cases in which one could almost construct a theory of a protective action of alcohol—a condition in which one protoplasmic poison can antagonize another. But such cases, even if competently studied, partake of the nature of a paradox and we feel certain that some fallacy is at work. The alcohol-syphilis association is considered by Lacapère in *La Presse Médicale* for July 3. He mentions that alcohol serves for the orientation of syphilis in a given subject and presumably race. Much of his remarks deal with the association in the various African races which dwell on colonial soil. He believes that alcohol causes sclerotic lesions of syphilis such as hepatic cirrhosis. This he associates with the hypertensive action of alcohol, despite the fact that many if not the majority of pathological anatomists do not see in alcohol a potent cause of arteriosclerosis, although it is admittedly a contributing cause to all but a few pathologists, and the clinician is inclined to look upon alcohol as at least an efficient cause. Arterial hypertension is said to be responsible for most visceral and nervous syphilitic lesions, but only in that it is the equivalent of overwork. The North African Arab is naturally free from neurovisceral syphilis and his lesions are essentially cutaneous and osseous, with which he is sorely afflicted. That the other type of lesions is seldom seen is attributed by the author to Mohammedan abstention from alcohol.

ALBUMINUROPHOBIA.

THIS expression would from analogy suggest fear of albumin in the urine only on the part of the affected subject, but as Pousson uses it in his article in *Le Bulletin Médical* for August 30 the fear may also affect the practitioner. The presence of albumin in the urine occurs in such a great variety

of conditions, many of which are mild and transitory, that the chances are against any grave significance unless the amount is large. This applies alike to medical and surgical conditions. It is taught in some quarters that albumin in the urine always means a leakage in the renal filter, but this is not the case, for the latter may retain its normal impermeability. This does not refer to the many forms of false albuminuria, but to cases in which the albumin comes directly from the blood. This is seen, for example, in certain circulatory disturbances. Loss of a little albumin is not *per se* a serious condition, but it may serve to call attention to some serious renal lesion and hence the necessity of excluding the latter. This is the viewpoint in insurance medicine which usually requires a postponement of assuming the risk until the clearing up of the urine. It is usually a great error to tell a patient that he has albumin in the urine, for, if a neurasthenic, he will be made worse and will lay greater stress on his urinary symptoms. In spermatorrhea when albumin is present this is especially true. In nephritic subjects albuminurophobia is often seen and it works adversely on the morale of the patient. The problem is a double one, for when, as often happens, a pharmacist fails to find albumin in the urine, the subject is greatly encouraged and ceases to worry about his urinary disturbances, being often lulled into false security.

News of the Week.

War Cost in Man Power.—A new estimate of the total cost of the war to the United States in man power is officially announced as 116,492 dead and 205,590 wounded, a total of 332,182. These estimates include losses to army and marine units on all fronts to September 1, 1919. Those killed in action totaled 35,585, or 11 per cent. of the entire list; died of wounds, 14,742; died of disease, 58,073; died of accident and other causes, 8,092.

Two Army Hospitals Close.—United States Base Hospital No. 2 at Colonia, N. J., has been ordered to be closed on October 15. The overseas wounded now stationed there, numbering about 1,000, will be removed to hospitals near their homes. General Army Hospital No. 1 at Williamsbridge, New York, will also be discontinued on October 15. Army hospitals, however, will continue to provide treatment for discharged soldiers, sailors, and marines for disabilities incurred in the line of duty and whose present condition is a reactivation of that disability or is consequent upon it.

Influenza Revisits Montevideo.—A recent report states that influenza cases are reappearing in Montevideo to an alarming extent and the medical authorities are taking the most drastic measures to combat the spread of the disease.

Doctors Strike for Minimum Salary.—A cablegram from London to the New York *Sun* tells of a doctors' strike in Ireland. According to this report the doctors of Dundalk, Ireland, have gone on a strike to enforce demands for a minimum salary of seven guineas (about $35) weekly for all public services. Their present salaries average $1,375 a year. The report states that many persons applying to the dispensaries for treatment have been refused.

Motor Corps Will Assist Health Department.—Health Commissioner Copeland announces that Col. Helen Bastedo, commander of the Motor Corps of America, has placed at the disposal of the Health Department the entire transport service of her organization. Dr. Copeland states that during the epidemic of influenza the services rendered by the Motor Corps through its aid in carrying doctors, nurses, invalids, food, and supplies, were a great help in the fight against the disease. It will be used in a similar way in the event of another epidemic and its offer of service will be taken advantage of immediately by the Department for the transportation of drug patients to the narcotic hospital on North Brother's Island.

Twenty Millions for Medical Education.—The General Education Board of the Rockefeller Foundation announces that it has received $20,000,000 to be devoted to medical education. The income is to be currently used and the entire principal is to be distributed within fifty years for the improvement of medical education in the United States. The General Education fund was organized in 1902. Its capital at that time amounted to $43,000,000. In 1915, its total fund had grown to over one hundred and seventeen million dollars, though it had distributed vast sums to educational institutions all over the country. Abraham Flexner, secretary of the General Education Board, states that a general survey of the medical schools of this country will be made, not only to determine which ones can be improved for the general good of the public, but to determine the needs of worthy schools. The policy will be to favor the upbuilding of the larger and stronger schools, notably those that have access to a wealth of clinical material. It is expected that large sums will also be devoted to the increase of hospital facilities.

Diseases Under Investigation at Rockefeller Institute.—During the autumn and winter the following diseases will be the subject of special study in the hospital of the Rockefeller Institute for Medical Research and patients suffering from these diseases will be admitted to the extent of the hospital facilities: (1) Acute lobar pneumonia and other acute pulmonary infections. It is requested that so far as possible these patients be transferred early in the disease in order that those suitable for specific treatment may receive the appropriate serum at the most favorable time. Patients suffering from influenza, bronchitis, bronchopneumonia, etc., will also be admitted. (2) Cardiac diseases. It is proposed to admit patients in the more advanced stages of heart failure. Such patients as show completely irregular pulse and are suffering from fibrillation of the auricles are especially desired. (3) Acute rheumatic fever. Patients with acute polyarthritis will be admitted and it is requested that these patients be referred to the hospital as soon as possible after the diagnosis is made. Children with recurring endocarditis, pericarditis, and myocarditis of supposed rheumatic origin and those with chorea, polyarthritis and acute cardiac complications will also be received. (4) It is desired to admit patients with acute nephritis and

also young persons suffering from chronic nephritis of moderately severe grade. The study of diabetes has been discontinued and no more patients suffering from this disease will be accepted at present.

College of Physicians and Surgeons Opens.—The College of Physicians and Surgeons of Columbia University held its opening exercises at the University on September 24. The opening address was delivered by the new Dean, Dr. William Darrach, whose subject was "Productive Medicine." His address not only emphasized the advances made in the prevention of disease among men in the army and the marvels of surgery effected for the benefit of the wounded, but laid particular stress on the physical improvement to be seen among returned soldiers. The American troops have come home weighing on an average ten pounds more than they did when they entered the army, but what they have learned in the camps of sanitation, hygiene, and right living will make every one of them, when he returns to civil life, an instructor of his friends and neighbors as well as practitioner of his new knowledge. It is of particular significance that Dr. Darrach whose personal work was largely with the wounded should have emphasized this phase of medicine.

The Wesley M. Carpenter Lecture.—The New York Academy of Medicine held its first stated meeting for the season of 1919-1920 on the evening of October 2. On this occasion Sir Arthur Newsholme, late Principal Medical Officer of the Local Government Board of England, and at present lecturer on public health at the Johns Hopkins School of Hygiene, delivered the Wesley M. Carpenter lecture, taking as his subject "The Increasing Socialization of Medicine."

Foreign Delegates Entertained.—The International Conference of Women Physicians, which has been in session in New York City since September 15, took a four days' recess from September 26 to October 1. During this time the foreign delegates took a trip to Boston and visited Harvard, Radcliffe, and Wellesley colleges and were entertained at a tea by Dr. Sarah Sweet Windsor at her country home. The foreign delegates to the conference have been invited by Mrs. Raymond Robins, president of the National Women's Trade Union League, to a tea on October 3 at the Cosmopolitan Club, N. Y., to meet the members of the National Women's Trade Union League.

Civil Service Positions on Interdepartmental Social Hygiene Board.—The United States Civil Service Commission announces the following positions on the recently created Interdepartmental Social Hygiene Board: Chief of Division for Scientific Research, salary $3,500 to $4,000. The duties of the appointee will be to assist the executive secretary of the Board as follows: In selecting colleges, universities, and other suitable institutions for scientific research, in sifting and judging researches proposed for discovering and developing effective medical measures in the prevention and treatment of venereal diseases, in applying the rules and regulations of the Board as required by law, in determining proper sums to be expended for researches, in operating an accounting system, in following up disbursements from the scientific fund to determine the value of the research done, in publishing reports of researches. Chief of Division for Educational Research and Development; salary $3,500 to $4,000. The duties of this appointee will be to assist the executive secretary as follows: In selecting colleges, universities, and other suitable institutions or organizations in which to develop and demonstrate more effective educational measures for the prevention of venereal diseases, in selecting colleges and universities, and other suitable institutions for sociological and psychological research for better methods of education and demonstration in the prevention of venereal diseases, in sifting and judging educational sociological and psychological researches proposed, in applying the rules and regulations of the Board as required by law, in determining proper sums to be expended for educational development, improved educational methods, and for sociological and psychological research in the various institutions selected in following up and checking up these investments, and in organizing and publishing reports from educational institutions and other organizations to which funds are allotted by the Board. Educational Assistant, salary $2,800 to $3,600. The duties of this appointee will be to assist the executive secretary in the activities of the Board carried on by means of allotments made to schools for negroes. Chief of Division of Relations with States, salary $3,500 to $4,500. The duties of this appointee will be to assist the executive secretary of the Board in the adjustment of allotments from the funds for the assistance of States through their departments of health in the treatment, prevention, and control of venereal diseases to prevent unnecessary duplication of activities; to coordinate with other similar activities of the Board and of the Government and in other ways to assist the executive secretary in cooperation with the states in the prevention of venereal diseases. Applicants should apply for Form 2118, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C. Applications will have to be properly filed with the Commission before November 4. The positions are open to both men and women. Competitors will not be required to report for examination, as the ratings will be based upon the competitor's sworn statements in their applications and upon corroborative evidence.

Three New Maternity Centers.—Within the past year three new maternity centers have been opened by the New York Maternity Center Association in Harlem and Yorkville. An educational campaign is being conducted in these neighborhoods to give help and advice to mothers. Other centers will be opened where they are found necessary. It is now planned to make the centers self-supporting, by charging small prices to the patients in the future, although this practice has not been put fully into effect at the present time.

Source of Oil in New York Waters.—A considerable discharge of heavy oils has been noted on the bathing beaches this summer. In order to determine the source of these petroleum products, the City Health Department, at the request of

the New York State Department of Health, made an investigation which resulted in the discovery of a tanker pumping "slops" overboard. Action has, accordingly, been commenced in the Federal Courts.

A Few Influenza Cases Reported.—The United States Public Health Service announced on September 27 that during the preceding week about 300 cases of influenza were reported from various parts of the United States. The disease has not reached epidemic proportions in any state and is mild in form. States reporting and the number of cases is as follows: Alabama, 20; Arkansas, 14; California, 51; Florida, 22; Georgia, 23; Kansas, 31; Kentucky, 13; Louisiana, 5; Maine, 5; Massachusetts, 62; Montana, 4; New Jersey, 20; New York, 31; Washington, 8.

Vacancies for Physicians.—The New York State Civil Service Commission announces competitive examinations for the following positions: Assistant Pathologist, at a salary of $1,800, in the State Institute for the Study of Malignant Disease, Buffalo. The position is open to men, women and non-residents. First Assistant Physician, Letchworth Village, Thiells, Rockland County, N. Y., at a salary of $2,600, open to men and women. Assistant Medical Officer, Department of Health Officer of the Port of New York, at a salary of $1,500 with maintenance. This position is open to men only. Applicants for these positions must be graduates of a recognized medical college and licensed to practice medicine in the State of New York. Application forms will not be sent out after October 13 and will not be received at the office of the Civil Service Commission, Albany, N. Y., after October 15, 1919.

Gifts and Bequests.—The Presbyterian Hospital, New York, has received a bequest of $2,000 by the will of Miss Mary M. Roberts.

Under the will of Margaret A. Howard of New York City the following institutions are recipients of bequests: St. Vincent's Hospital, $5,000; the New York Foundling Hospital, $1,000; Columbus Hospital, St. Elizabeth's Home for Crippled Children, St. Ann's Convalescent Hospital, New York Institute for the Blind, Home of Rest for Consumptives, and New York Skin and Cancer Hospital, each $500.

The will of General Horace W. Carpenter, trustee of Columbia University, bequeathes the bulk of his estate of about $3,000,000 to that institution. Of this sum $200,000 goes to the Presbyterian Hospital and $80,000 to Sloane Maternity Hospital.

Dr. Homer E. Smith has removed from Norwich, N. Y., to 276 Madison Avenue, New York City. He has been appointed assistant surgeon to Mr. Knapp Memorial Hospital, and will limit his practice to diseases of the eye.

Dr. George M. MacKee has removed to 170 West Fifth-ninth Street, New York.

Major General William C. Gorgas arrived at Guayaquil, Ecuador on September 24, aboard the Peruvian cruiser Lima, from Peru, and left soon after for Panama. It is announced that Guayaquil is now entirely free from yellow fever.

British Ministry of Health Helps Solve Housing Problem.—The British Ministry of Health has embarked on a plan to convert army camps in various parts of the country into housing colonies. Experiments have proved that these huts make good homes for working men and the people buying the huts soon form congenial communities. These huts have been purchased by various municipal authorities, at the suggestion of health authorities, fitted with electric light, and connected with central heating plants. The large military hospital at Cambridge has been taken over by the college authorities and will become a communal settlement for students.

Argentina Establishes Tuberculosis Sanatoria.—The Government of the Argentine Republic has launched a campaign against tuberculosis by the establishment of sanatoria in various parts of the country and at the same time has adopted measures to prevent the spread of the disease among the population. Argentine has an ideal climate for the treatment of tuberculosis which brings many thousands of patients to the country for treatment each year and, in addition, tuberculosis has been spreading rapidly among the younger portion of the population, thus making the situation one of vital concern to the country.

The Southern Medical Association will hold its annual convention in Asheville, N. C., Nov. 10 to 13 inclusive, under the presidency of Dr. Lewellys Barker of Baltimore.

Medical Society Elections.—The New England Association of Jefferson Medical College, at its eleventh annual meeting held in Boston, Sept. 18, 1919, elected the following officers for the ensuing year: *President*, Dr. E. Winfield Eagan, Brockton, Mass.; *Vice-President*, Dr. W. T. Beal, Stonington, Conn.; *Secretary*, Wallace P. MacCallum, Boston; *Treasurer*, Dr. Frank I. Payne, Westerly, R. I.

The Utah State Medical Association, at its annual meeting held in Salt Lake City Sept. 10, 1919, elected the following officers for the ensuing year: *President*, Dr. George E. Robinson, Provo; *Secretary*, Dr. William L. Rich, Salt Lake City; *Treasurer*, Dr. Jane W. Skolfield, Salt Lake City.

Obituary Notes.—Dr. August Hoch, formerly of New York City, who removed to California two years ago because of ill health, died of nephritis in the University Hospital in San Francisco on September 23, aged 51 years He was a graduate of New York University in 1890, and later studied at Johns Hopkins. He was at one time attached to the staff of the McClean Hospital in Boston and later was first assistant at the Bloomingdale sanitarium. Following that he was for seven years the director of the Psychiatrical Institute on Ward's Island. He was a member of the American Neurological Society, the American Psychiatrical Society and the American Psychopathic Society. He was also chief of the Psychopathic Dispensary at Cornell Medical School.

Dr. Junius E. Warinner of Richmond, Va., ditd on August 29, at the age of 59 years. He was a graduate of the Medical College of Virginia in 1884.

Dr. James A. Dickey of Bristol, Tenn., died on September 4, at the age of 70 years. He was a graduate of the medical department of the National University of Arts and Sciences, St. Louis, in 1889. He had served for several terms as mayor of Bristol.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Sept. 3, 1919.

The Prevention of Venereal Disease.—The new Ministry of Health of Great Britain recognizes the venereal question is predominant and makes it one of the early subjects of investigation. The chairman of the committee on Infectious Diseases in connection with Demobilization has addressed a memorandum dealing with prophylaxis against venereal disease. In this memorandum is discussed the advisability or otherwise of making available officially for the civil community what is commonly known as "the packet" method of prophylaxis against venereal disease, which method has been spoken of favorably by medical officers for its successful effects among soldiers. The chairman states that the opinions of members of the committee are against the use of these packets because their issue tends to give rise to a false sense of security and further that the issue of packets results in many individuals using them for self treatment after infection; they are not intended for this purpose and are ineffective. According to the committee their use may be definitely stigmatized as harmful, since they delay diagnosis and the application of prompt treatment. The representatives of the different departments who assisted the committee at various times in their deliberations on the subject ask that there should be recorded their unanimous view that the true safeguard against these diseases is individual continence. This implies a sound public opinion and a healthy national tone. The memorandum finally says that the committee set out to examine the evidence placed before them from the scientific and medical points of view, and it is strictly in the spirit that its members desire to record it as their opinion that the irreplaceable effect of the moral factor has been too frequently neglected or forgotten. The main feature of the memorandum which has been issued as a parliamentary paper is that it advises against the official application of the prophylactic measure known in the army as the packet system.

Post Graduate Education in London.—The scheme for rendering post graduate medical education in London efficient, appears now to be moving apace. The Fellowship of Medicine, which largely owes its inception and progress to the energy of Mr. Philip Franklin an American surgeon of Wimpole Street, London, ably aided by the two other joint secretaries Mr. J. Y. W. MacAlister and Mr. Herbert J. Paterson, has the matter well in hand and will no doubt have the collaboration of the Post Graduate Association. The Fellowship of Medicine will now probably carry the scheme through and as Dr. Arthur Latham says in a letter to the *British Medical Journal*, August 23, 1919, "the schemes of the two bodies will be successfully merged." The foundation of an American hospital in London referred to in a previous letter should go far toward fulfilling the purpose for which it was conceived, to establish a home and hospital and hospital training, if desired by American medical men and students in London, and above all to promote good feeling between Americans and Britishers. The reasons why, if the various hospitals and medical schools are unified and organization is successfully carried out, London should be the ideal post-graduate medical center, at any rate for Americans and for medical men from the Dominions, are too clearly apparent to need recapitulation. The sooner all difficulties are smoothed over the better will it be for all concerned. If a beginning is not quickly made, the men who require immediate experience will look elsewhere and London will have lost, at least, to a great extent, a unique and unrivalled opportunity. However, the outlook seems to be bright, thanks to the efforts of Sir Arbuthnot Lane, Sir St. Clair Thomson, Sir William Osler, Mr. Herbert J. Paterson and especially to the labors of Mr. Philip Franklin. The fear of rivalry on the part of New York which is said to aim at the eminence of being the largest and best post-graduate medical center of the world, need give rise to no apprehension. There is plenty of room for an immense medical center in the old world and in the new world. In fact, it should be to the advantage of the two largest sections of the English speaking peoples that there is reciprocity in medical education. Each can learn a good deal from the other in medical and surgical matters, and nothing could further good feeling more effectively than communion and exchange of ideas

Work for Disabled Men.—Sir R. S. Horne, British Minister of Labor, has circularized the trade unions of the Kingdom regarding the provision of employment for disabled ex-service men. In asking for cooperation and sympathy, he outlines a scheme for the absorption of all crippled men by an equitable distribution of them among the several industries they represent. He states that about 5 per cent. of the total, about 100,000, still require work, one-half of them being in hospital. It is recognized, the Minister says, that a special training in suitable industries provides the best means of the final solution of the problem, but in the meantime employment must be found. While the provision of training facilities is being pressed on, the Ministry was but asking the industries to take 5 per cent. of the disabled men. Seven-eighths of the disabled men had already been placed in industries thus discharging the debt of honor to ex-fighters.

Obituary.—The death has been announced recently of Dr. William Smith Greenfield, F. R. S., Edin., at the age of 73, who was Emeritus Professor of Pathology and Clinical Medicine at Edinburgh University, from 1881 to 1912.

6. **Hepatic Spasm and Hypersecretion.**—Arnold H. May describes a condition which he calls hepatic hypersecretion and spasm, which he has seen in a very few persons but has never seen described in textbooks. It does not seem to be associated with pathological conditions of the gallbladder, ducts, or liver cells, and it is doubtful if it is of nervous origin. The hypersecretion of the liver is periodical and stasis of bile in the gallbladder exists, enlarging this organ far beyond normal. Associated with this condition there is some occlusion of the gall duct, which, in a sense, is not pathological, as the occlusion is temporary, and is undoubtedly due to a spasm of the secretory duct of the liver in and about that part of it which enters the duodenum. This spasm seems to be correlated with hypersecretion of the liver and a vicious circle is established, indicated by too much bile to be excreted into the duodenum; regurgitation of it into the gallbladder; distention and dilatation of the gallbladder, and occasionally the ducts; a release of the spasm; a temporary opening of the ducts with the flow out of the accumulated bile, and a cessation of the hypersecretion. The whole phenomenon is repeated periodically. The clinical symptoms manifested are sudden pain, mild in character, beginning in the right hypochondrium, becoming more intense, and radiating toward the appendix; a feeling of fulness or heaviness over the epigastrium and upper abdomen; nausea only occasionally; more or less marked gas formation, with eructations; occasional attacks of vomiting and jaundice in the more severe attacks. The blood may be normal or may show a slight anemia; secondary leucocytes are normal. The writer has observed the condition in persons over forty years of age, but thinks that in all probability it occurs in younger persons. A differential diagnosis is possible if the transitory nature of the attack is taken into consideration and the *x*-ray findings are negative.

3. **An Experimental Study of the Effects of Duodenectomy.**—F. C. Mann and K. Kawamura present a preliminary report of an investigation of the effect of duodenectomy in dogs (1) to determine whether the duodenum is absolutely necessary to life, and (2) to determine its rôle in the functioning of the gastrointestinal canal. They describe a new one stage operation which they found applicable to dogs and animals of certain other species, and state that their results fully corroborate those of the more recent investigators. The animals quickly recovered from the operation and, with a few exceptions, have remained in excellent health. Their general condition has been good; their weight has usually increased or remained stationary. A few of the animals steadily lost weight and strength after the operation. At necropsy or exploratory operation on these animals, a dilated common bile duct and marked infection of the entire biliary tract were usually found. Evidently transplantation of the bile duct and the minor and major pancreatic ducts, as done in these experiments, did not restore a condition sufficiently normal to prevent infection. Examination of the blood to determine the cell count, hemoglobin, carbon dioxide combining power and hydrogen ion concentration did not reveal anything abnormal. Examination of the gastro-intestinal tract by the roentgen ray, employing a barium meal, showed in general, no difference in the passage of the barium meal in the duodenetomized and in the normal dogs. Roentgenograms of the gastrointestinal tract seemed normal. Experimental duodenectomies were also performed on the cat, goat, hog, and monkey (Rhesus), and all the animals, with the exception of one dog, are in good condition. No data have been secured to show that the duodenum is of great importance in any of the species used.

8. **Iodine Tinctures—Water Soluble.**—Torald Sollmann has made a series of tests to ascertain the correctness of the claim of certain preparations of iodine for superiority over the official preparation on the basis of the allegation that the potassium iodide in the official preparation causes a local irritant action which is avoided in the nonofficial preparations. Various iodine preparations of an equal iodine content were applied to the skin and the experiments were extended in other directions. From the evidence furnished by these investigations, Sollman concludes that the presence of potassium iodide in the official tincture of iodine does not seem to render this preparation more irritant. On the contrary, it is somewhat less irritant to the skin, and much less precipitant to proteins, than the simple alcoholic tincture or the "misclble tinctures." The more even spreading and the more rapid coagulation of protein render the simple alcoholic solution of iodine probably the best for the disinfection of the skin; while the delayed protein precipitation by the U. S. P. tincture would probably render this somewhat superior for the disinfection of open wounds. The "water soluble tinctures" do not appear to have any material advantages.

5. Perithelioma Simulating Pancreatic Cyst. R Eccles Smith.
6. Avoidance of Relapse in Gonorrhea. Charles Russ.

2. **Rapidly Fatal Spinal Caries.**—J. Rupert Collins describes three cases of rapidly fatal spinal caries met with during the three years in which he was officer in charge of the medical division of 30th General Hospital, B. E. F., and states that he has been unable to find a record of similar cases in the literature to which he has access. In each case the anamnesis was taken with the greatest care and there was no recollection of anything to point to old caries. Each of these three men appeared robust and gave a good previous health report, with the exception that the second gave a history of pains in his back. The illness of the first lasted six days, that of the second fifteen days, that of the third nine days. The onset in each case was swift and without warning. In the first case the patient found himself unable to walk to the medical hut. This man had had six months' service, the second had a year and five months, and the third two years and three months. At autopsy all three cases showed in addition to the spinal caries evidence of tuberculous involvement of the lungs. The writer suggests that cases of this description might become of considerable medicolegal importance in civil life, as, had there been a history of a blow or strain, it would be difficult to prove to the satisfaction of a jury that the acute disease of the spine was not due to the injury.

3. **The Comparative Value of Novarsenobillon by the Intravenous and Intramuscular Methods.**—L. G. Leonard relates his experience with 428 cases of primary and secondary syphilis, part of them treated with novarsenobillon intravenously and part treated intramuscularly. The course of novarsenobillon given

in all cases was the same, being the prescribed army course. Of the early and medium primary cases, numbering 79, 26 were treated intramuscularly and 53 intravenously, with the result that 100 per cent. negative Wassermann reactions were obtained by both methods. Of 88 late primary cases, 37 were treated intramuscularly and 51 intravenously, with the result that 94.6 per cent. of those treated intramuscularly yielded negative Wassermann reactions, while 90.2 per cent. of those treated intravenously gave negative reactions. Of 72 early secondary cases, 30 were treated intramuscularly and 42 intravenously, resulting in 100 per cent. negative Wassermann reaction following the intramuscular injections and 90.5 negative reaction following the intravenous treatment. Of 189 later secondary cases, 75 were treated intramuscularly, with 90.7 negative Wassermann reaction, and 114 were treated intravenously with 81.6 negative Wassermann reactions. In other words, of 168 cases treated intramuscularly 95 per cent. yielded negative Wassermann reactions, while of 260 cases treated intravenously 88.5 per cent. yielded negative reactions. It is thus seen that good results were obtained with both methods, though the results with the intramuscular method were the better. This is due no doubt to the slower and more certain absorption with a consequent lower excretion with the intramuscular method. The great objection to this method is the pain and stiffness complained of after the injection and the writer feels convinced that unless some device can be found to counteract these, it is a method that is impracticable for routine work in private practice or even in clinics. The fact that 100 per cent. negative Wassermann reactions resulted by either method in the early and medium primary cases emphasizes the importance of early diagnosis and treatment. Of 83 tertiary cases, 66 were given intravenous injections, and 17 were given intramuscular injections. In over 50 per cent. of those treated intravenously strongly positive Wassermann reactions changed to either positive or negative after a single course of treatment, and this was somewhat better than the results obtained by the intramuscular method in tertiary cases. The intramuscular method seemed to have the greater number of side effects, especially headache and vomiting, but Leonard is inclined to believe that these were produced by the hypodermic of morphine that preceded the intramuscular injection of novarsenobillon. He brings out the fact that before the influx of infected troops from the East only a few cases of early syphilis occurred at his depot and that immediately after this influx syphilis increased enormously, and believes that the best means for preventing the spread of venereal disease at the present time lies in early diagnosis and early treatment, and, as regards the army, periodical "short arm" inspection of troops, as at present carried out. This, of course, cannot be applied to the civil population, but "quackery" and counter prescribing should be more rigorously dealt with to prevent serious delay in commencing proper treatment.

1. Food Factors in Gastroenterology.—Lafayette B. Mendel emphasizes the fact that rational dietetics founded upon the newer knowledge f the chemistry of foods and nutrition has not yet received the discriminating study and advocacy on the part of practical clinicians that its importance unquestionably warrants. The current attitude of aloofness from sane and helpful dietetics in medical practice is largely engendered by ignorance and indifference, conditions which the recent progress in this field should help to dispel. The widely divergent methods now in vogue in the treatment of gastric ulcer—methods which range from enforcement of complete physiological inactivity and absence of food in the upper alimentary tract as the one extreme, to liberal feeding, intended secure better healing through improved general nutrition, as the other extreme—illustrate the place which a fundamental understanding of food factors, should have in a rational gastroenterology. Indeed, there are few, if any, specialized departments of medicine which would fail to benefit by greater attention to the fitness of the body as a whole. Among the innovations of viewpoint which the newer physiology offers as worthy the attention of the gastroenterologist the modern conception of secretion becomes conspicuous. If the various chemical stimulants to secretion, particularly as they occur in our diet ingredients, were better known and appreciated, the information would find more frequent application, particularly in the promotion of gastric secretion. Selected foods and related substances may before long be expected to accomplish for secretion some of the effects which drugs are at present often called upon to bring about. The writer suggests that dietary deficiencies, such as are exemplified by the lack of suitable vitamines in the ration, may affect the gastroenteric tract quite as probably as other parts of the organism which are represented in the now recognized so-called deficiency diseases. The gastrointestinal symptoms in pellagra afford a specific illustration of this. At the present stage of our knowledge the gastroenterologist cannot afford to overlook the possible rôle of the vitamines in the functions of those parts of the organism with which he is most directly concerned. The possible bearing of vitamines on the problem of appetite and alimentary well-being should not be overlooked by those who are interested in the physiology and pathology of the gastroenteric tract. In considering the rôle of albuminous substances in nutrition the gastroenterologist is confronted with the unlike digestibility of proteins from different sources. There are objections to the use, as nutrients, of proteins known to be difficult of digestion because either of chemical composition or physical texture. On the other hand, it must not be assumed that every protein which is digested with readiness and completeness in the alimentary tract is on this account an ideal component of the ration. When the proteins of wheat are fed in combination with about one-third of their weight of the proteins furnished by eggs, meat, or milk, these cereal proteins are so greatly enhanced in value that flour is thus used most advantageously. Adequate nutrition means something more than calories and digestible nutrients. A study of the inorganic elements of our diet has shown that calcium and phosphorus are essentials while the need of other familiar inorganic elements appears to be unexpectedly small, and that it is unnecessary to consider the presence of calcium phosphorus and iron, for example, in natural foods to the degree that is currently believed. Authorities are concordant in suggesting that diet can probably be made a more potent factor than are bacterial cultures in regulating putrefactive conditions in the bowel. Dietetics offers no cure-all to the gastroenterologist, nor does any other mode of therapy. Calories, proteins, vitamines, acidophilic bacteria—these furnish viewpoints from which important problems of practice may be examined. The student of foods and nutrition is wont to be reminded that "a little knowledge is a dangerous thing." This the writer says is doubtless true but he cannot gain the conviction that utter ignorance is a safety valve.

4. The Murmurs of Mitral Stenosis and of Aortic Regurgitation.—Harold E. B. Pardee describes his study of 36 patients with valvular disease at the Military Heart Hospital at Colchester, England. The cases were examined under eight different conditions, to determine which, if any, were most favorable for bringing out the characteristic murmurs: (1) standing up-

right; (2) standing upright with the chest held in forced expiration; (3) standing with the trunk bent forward at an angle of 45 degrees to the horizontal; (4) lying on the back; (5) lying on the back with the chest held in forced expiration; (6) lying on the left shoulder and side, the trunk turned so as to be about 45 degrees from the horizontal; (7) after exercise, hopping on both feet; the patient was listened to standing upright; (8) lyin on the left side, as in (6). He found that the best conditions for hearing the murmur of mitral stenosis are present after exercise and especially when lying on the left side after exercise. Without exercise the left lateral and the bent forward positions are by far the most favorable. The dorsal position is better than the erect in about 45 per cent. of the cases, though in 36 per cent. it is less favorable. All of these positions should be used in listening to doubtful cases, and especially the positions after exercise, without which a negative diagnosis should be made. The crescendo murmur is not present in all cases of mitral stenosis, and is best elicited by the left lateral position after exercise. It may be present for the first few beats only even under these conditions. In any one position and especially in the erect positions, some cases may show nothing at all to suggest mitral stenosis, yet in the more favorable position a typical combination may develop. This observation is very important in its bearing on the diagnosis of early cases These variations of the murmur with position should be carefully borne in mind in following the progress of individual cases over a period of months or years. Each examination should be made under the same conditions. The best conditions observed for hearing the murmur of aortic regurgitation were the erect bent forward position, the erect position in forced expiration, and the erect position after exercise. It seems probable that the bent forward position after exercise would be better still than any of these. The murmur varies only in intensity and not in quality. A negative diagnosis should never be made unless direct auscultation is used. Very faint murmurs due to aortic regurgitation were heard near the sternum, in the fourth left interspace, the third left interspace, and these three areas in the order named were the most common areas of maximum audibility of the plainest murmurs. As a whole these special procedures for examination have proved to be decidedly valuable in the early recognition of early or obscure cases of valvular disease. The use of the different positions is very instructive to the examiner, giving him an idea which cannot be obtained otherwise of the degree of disturbance of the blood currents in the heart. This is particularly the case with mitral stenosis, and certain minor abnormal diastolic sounds are pointed out which are believed to presage the more typical murmurs of this lesion.

6. Glycosuria in Pregnancy.—Malcolm H. V. Cameron describes four cases of glycosuria which he has met among 468 obstetrical cases and also mentions two in the practice of Dr. Victoria Reid and two in that of Dr. D'Arcy Frawley upon which he offers certain clinical observations. He brings out the point that dysfunction of the pituitary gland may result in acromegaly and this has frequently associated with it a condition of glycosuria. Pregnancy demands a hyperplasia of the thyroid gland and of the hypophysis, as is well known. The generation of the autocatalyzer, by which growth is maintained or accelerated, belongs to the anterior lobe of the pituitary body, as Brailsford Robertson has shown. The provision of this catalyzer demands a hyperplasia, which may run beyond the necessities of the case or which may involve the posterior lobe of the pituitary body, in which case, acromegaly may, presumably, develop. The writer has apparently seen this occur in one case. The hyperplasia as it affects the posterior lobe results in a condition of hyperglycemia with decreased carbohydrate tolerance, and this added to the normal hyperalimentation of pregnancy, may result in glycosuria. Should the hyperplasia affect the pars nervosa chiefly, a polyuria, without glycosuria or diabetes insipidus, will follow. Thus it appears that the relation between diabetes insipidus and glycosuria depends upon the very narrow margin of chance, that in a general hyperplasia of the pituitary body in its posterior lobe the pars nervosa acquires a stimulation greater than does its epithelial envelope. Again, should the epithelial portion of the posterior lobe fail to take part in the general hyperplasia or should its secretion be hindered in its entry into the cerebrospinal fluid, a condition resembling hibernation results. Should the hyperplasia affect chiefly the anterior lobe, the hyperglycemia mentioned will not occur, and thus, though acromegaly may develop to an extent, glycosuria will not be its accompaniment, although acromegaly usually is associated with glycosuria as the whole gland is affected consistently. The practicaly conclusion to be deduced from the consideration of the group of cases reported is that the finding of a reducing sugar in urine from a pregnant patient is a serious matter. Where it exists true diabetes may be about to manifest itself or may be already in existence. A regulation of the diet more or less strict will keep the symptoms in abeyance. A careful selection of anesthetic and any possible means to lessen the shock of delivery will perhaps prevent the onset of such changes in the endocrine gland system, already strained beyond the normal, as is indicated by the glycosuria and which might result in diabetes. The only means of arriving at a conclusion as to whether a diabetes is under control in a pregnant woman is by the estimation of sugar in the blood. The method of doing this is simple if one uses a proper calorimeter. The ingestion tests for carbohydrate tolerance would arrive at approximately the same conclusions but they are difficult of execution and disagreeable to the patient.

Stomatology and Italian Science.—Dental hygiene played a rôle in Italy from very early times. As far back as Dante's epoch the cautery was used for dental infections and after syphilis caused the widespread use of mercury it was the Italian who modified hygiene of the mouth to suit the new conditions. The study of anatomy and development of the teeth was pursued by Leonardo da Vinci, Ingrassia, Eustachius and Fallopius. In 1807 Fonzi invented porcelain teeth, platinum and gold crowns and the rubber palate. This pioneer visited Paris, London, Madrid and Petrograd in the interest of his discoveries. An eminent colleague was Cornelio, while another Italian contemporary actually published a monthly magazine on Stomatology a century ago. This was Platschick, sometimes termed the founder of modern Italian stomatology.—*La Riforma Medica.*

Generalized Horsepox.—An aged man whose work consisted in caring for diseased horses was exposed to an animal who suffered from an intense disseminate eruption with a constitutional reaction. After an incubation period of about three weeks he began to develop a rash, which began on one wrist, and spread to the fingers below and arms above, encroaching upon the thorax. In these regions there was more or less tendency to coalesce, but elsewhere the eruption was sparse. There was an intense conjunctivitis of one eye. Lesions were polymorphous, vesicles and pustules, some umbilicated. Blackish scabs and crusts were seen. The diagnosis was horsepox, or more literally generalized, accidental vaccination. These lesions are known to spread by autoinoculation only, for the existence of a blood infection has been disproved.—*Bulletin de la Société Française de Dermatologie et de Syphiligraphie.*

Book Reviews.

Sir William Turner, K. C. B., F. R. S. Professor of Anatomy and Principal and Vice Chancellor of the University of Edinburgh. A Chapter in Medical History. By A. Logan Turner, M. D. Edinburgh and London: William Blackwood and Sons, 1919.

Dr. Turner's biography of his father has to do especially with the subject of the progress of medical education during the lifetime of the deceased. The latter in 1910 was approached by a publisher to undertake a work on this very subject but declined, and the son now combines an account of the same with a biography of the father. The book is therefore a notable contribution which, however, is not suitable for an extended review in these columns. Three chapters devoted to the elder Turner's labor on anthropology are of much interest and the American reader will learn the part played by the late Andrew Carnegie in fostering medical education in Scotland.

A Treatise on Orthopedic Surgery. By Royal Whitman, M. D., M. R. C. S., Eng., F. A. C. S. A Director of Military Orthopedic Teaching; Chairman of the Medical Advisory Board for Orthopedics in New York City; Associate Surgeon to the Hospital for Ruptured and Crippled; Orthopedic Surgeon to the Hospital of St. John's Guild; Consulting Orthopedic Surgeon to St. Agnes's Hospital for Crippled and Atypical Children, White Plains, to the New York Home for Destitute Crippled Children and to the New York State Board of Health; Member of the American Orthopedic Association; Corresponding Member of the British Orthopedic Society; Member of the New York Surgical Society, Etc. Sixth Edition, Thoroughly Revised. Pp. 914 illustrated with 767 engravings. Philadelphia and New York: Lea and Febiger, 1919.

As we said when reviewing the previous edition (Medical Record, January 26, 1918), this is a real orthopedic surgery and not a mere compilation of pathology, signs, and symptoms of orthopedic conditions with exhaustive directions for the application of plaster and braces and with occasional brief suggestions for knife surgery. It is true that many and perhaps most of the conditions that have been considered to belong strictly to the field of orthopedic as opposed to general surgery are best treated by nonoperative methods; but Whitman does not hesitate to advise operation when that would give the best and quickest results.

According to the preface, Whitman considers that the chief distinction of orthopedic surgery lies "in the constant purpose to prevent or to correct deformity and to preserve or to restore function, a purpose that governs treatment from the beginning and to the end. . . . Thus he has been at some pains to describe systematic methods of examination that lead to early diagnosis; to explain the significance of the symptoms and physical signs that establish it; to indicate in natural sequence the principles of treatment and to describe simple and direct methods by which these principles may be effectively applied."

The author has succeeded admirably in carrying out his purpose. By thorough revision the book has been brought up to date; and those who have orthopedic cases to handle will find it a valuable guide. More space should have been given to bone-graft surgery, even though the author may consider that this latter subject belongs more properly to the realm of general surgery. In reviewing the previous edition we severely criticized the section on military orthopedics. We are glad to see that this section has been entirely rewritten and much enlarged, so that its value is now more in keeping with that of the rest of the volume.

Trench Fever, a Louse-Bourne Disease. By Major W. Byam, R. A. M. C.; Captains J. H. Carroll, U. S. R.; J. H. Churchill, R. A. M. C. (T.); Lyn Dimond, R. A. M. C.; V. E. Sorapure, R. A. M. C.; R. M. Wilson, R. A. M. C., and LL. Lloyd, R. A. M. C. (T.). New York: Oxford University Press, American Branch, 1919.

The demonstration of the relation of the louse to trench fever is a piece of work as complete and as admirable as that which demonstrated the connection between yellow fever and the mosquito. The history of this investigation, with its results and details of the experiments by which these results were accomplished, is given in this volume. The conclusions are now familiar to every reader of the newspapers, almost to every schoolboy. It is known that the "cootie" is the immediate agent in the transfer of the infectious material, usually by way of his intestinal contents which are scratched into the wound of the bite. The organism, whatever its nature, goes through a period of development in the body of the louse before it again becomes infectious for man. But the whole fascinating story is in this book. While one admires the genius and energy of the investigators who succeeded in solving this problem, one must have the greatest respect for those many unnamed volunteers who allowed themselves to be bitten by the lice and who all, practically, contracted the disease, and thus enabled the experiment to terminate successfully.

The After Treatment of Wounds and Injuries. By R. C. Elmslie, M.S., F.R.C.S., Brevet-Major R.A.M.C. (TF), Special Military Surgical Hospital, Shepherd's Bush; Surgeon-in-Charge of the Orthopædic, Physical Exercise, and Massage Departments, St. Bartholomew's Hospital; Surgeon to Out-Patients, Metropolitan Hospital; Orthopædic Surgeon to Queen Mary's Hospital, Roehampton; Consulting Orthopædic Surgeon to the Foundling Hospital and National Children's Home and Orphanage. Philadelphia: P. Blakiston's Son & Co., 1919.

This book does not deal with the after treatment of wounds and injuries of all regions, as encountered by the general surgeon, but is simply a treatise on the after treatment of such wounds and injuries as may be handled by the orthopedist, and covers particularly injuries to bones, joints, muscles, tendons and nerves.

The author gives the results of the experience acquired during two and a half years' work in a military orthopedic hospital, states the principles he has been led to adopt, and give sufficient examples of methods and results to guide others in their practical work. He considers that the object of the orthopedic surgeon in traumatic cases is to restore the maximum functional utility to the damaged part by the simplest and most expeditious methods. The procedures to bring this about are: "(1) The repair by surgical means of the damaged part, so far as that is possible. This repair includes the suture of skin, excision of scars, suture and repair of nerves, muscle and tendons, restoration of continuity in bones in good alignment, and such surgical treatment of joints as will secure stability and mobility. (2) The replacement of functions which are definitely lost, by the use of the remaining healthy parts, by such means as tendon grafting, tendon fixation, and fixation of joints. (3) The restoration of function by methods of physiotherapy, including treatment by massage, movement, baths, and by gymnastic reeducation, and including also the functional use of the limb in the course of active work. (4) The replacement of function by the fitting of an appliance, such as an artificial limb."

With these as fundamental principles, the author takes up the wounds and injuries of the different structures and regions and tells how to treat them. Osteomyelitis, ununited fractures, stiff and flail joints, amputations and their after treatment, tendon transplantation, the diagnosis, operative and nonoperative treatment of nerve injuries—these and many other subjects are touched upon briefly or in detail in accordance with the relative importance of the subject under discussion. There are also chapters on splints and surgical appliances, plaster-of-paris technique, and physiotherapy. There is nothing regarding the treatment of wounds and injuries of the head, chest, and abdomen; practically nothing moreover as to the treatment of wounds of the soft parts as such, but only in so far as functional disturbances result and operation or other forms of treatment are suggested for their improvement or cure. The book is evidently intended purely for the orthopedic surgeon and the title should be amended in some way to show that fact. As a guide to the orthopedist in traumatic cases, Elmslie's book should be a distinct help.

Society Reports.

AMERICAN THERAPEUTIC ASSOCIATION

Twentieth Annual Meeting, Held at Atlantic City, N. J., June 6 and 7, 1919.

DR DOUGLAS VANDERHOOF OF RICHMOND, VA., PRESIDENT, IN THE CHAIR.

(*Continued from page 568.*)

Angina Pectoris.—Dr. H. C. GORDINIER of Troy, N. Y., read this paper. (See page 575.)

Auscultatory Percussion in Diagnosis of Cardiac Lesions.—Dr. W. F. MILROY of Omaha, Neb., presented this communication. (See page 581.)

Therapeutic Problems in Pulmonary Tuberculosis, with Disturbance of the Cardiovascular System.—Dr. ERNEST ZUEBLIN of Cincinnati presented this communication. (See page 584.)

Rest in Tuberculosis.—Dr. FRANCIS M. POTTENGER of Monrovia, Cal., made this presentation. So simple a measure as rest was little understood in the treatment of tuberculosis. Brenner had thought that tuberculosis was due to a small heart, and that exercise was the proper treatment. His results were good. Evil effects were not noted. Detweiler noticed the evil effects of exercise and went to the other extreme in regard to rest. In this country the profession were apt to follow Brenner, in Europe, Detweiler. The speaker had tried the exercise plan and when he found it did no good he stopped it and tried rest instead, and began to get good results. One man, a doctor who had been at sanatoriums in Toronto, San Antonio, and Aiken, treated by exercise, got no better. It would seem that doctors got a worse deal than anyone when they got sick. When seen by the speaker, and advised to rest instead of exercise, he exclaimed, "Thank God! I have found a man who understands how I feel." The question of rest in tuberculosis must be based on something more definite than temperature. It was a question of conserving the patient's strength, and they should have enough energy left at the end of the day to take care of the normal demands of the day, plus the extra demands of the disease, plus reserve power. Their fighting power must be conserved to the utmost. Rest and exercise must be applied in the right way. It was not enough to tell the patient to rest, as if he understood how it should be carried out. Most physicians understood very little of the minutiæ of the rest treatment. Twenty-five per cent. more energy was required for rest in a chair than for rest in bed; sitting up and conversing required 45 per cent. more energy. The difference between sitting up and lying down would turn the scale in many cases. There was no one great remedy for tuberculosis but there were a lot of little things, and if enough of these little things were done the scale would be turned. Hydrotherapy, heliotherapy, tuberculin—not one of these things would do more than 10 per cent. of the cure, but if enough aids were added, the sum would effect the cure. Another point in regard to exercise was that it increased the strain upon the heart, already burdened by the effects of tuberculosis; exercise also increased the acidity of the blood, and favored breaking down of the enzymes, and autolysis. What was the basis of rest and exercise in tuberculosis? If rest was necessary during the period of clinical activity of the disease, when was one to put the patient on exercise? Some writers stated that a rise of temperature meant an activity of the disease, yet there might be an implantation of the bacilli and no clinical symptoms might take place for four or five years later. Then rapid processes would occur and the temperature curve would go up and down. The patient might have a high temperature and cough one week, and not the next. There was a great difference between the clinical and the pathological activity in tuberculosis, and one must not consider days and weeks. Temperature meant nothing as far as the activity of the disease was concerned. Tuberculosis might open up and heal and take a life time to develop. When the patient's resistance was lowered the bacilli had the chance to gain an ascendency. What then was the picture of active tuberculosis? It was the sum of experience based on a long period of time. The patient had to be watched for weeks and the picture as a whole studied. When one could feel that the sogginess in the lungs was disappearing (not the râles, for they might last as long as the patient lived) that patient was becoming a quiescent case and could be put on a different régime than in the active stage. Every patient seen by the speaker was put to bed and kept there as long as there was any question of active tuberculosis; this might be for months, sometimes for a year, or two years. Temperature was never taken as a guide. The patient and his condition were taken as a guide. Then when the disease became quiescent, he began to exercise by sitting up, perhaps for five or ten minutes, increasing to twenty or thirty minutes, morning and afternoon, then two or three hours. When he could sit up two or three hours without tiring, exercise was started, walking perhaps 50 or 100 feet a day. This graduated exercise meant the rehabilitation of the patient, and it was the aim to bring him to the point where he could walk from two to ten miles a day without getting tired, and without toxemia. If one could not do that, one had failed. Another point was that mental rest was of as much importance as physical rest. One had to prepare a régime that would keep the attention of the patient and keep control of his mind as well as of his body. Something should be done for them all the time, so that they were kept contented. Even if they had been business men, they would take interest in watching themselves improve. The patient had to be treated, not only the disease. The patient had the disease, not the disease the patient. Rest and exercise had to be adjusted to each individual. In conclusion the sum of the matter was to treat by rest until the disease was inactive and then to bring up exercise until the patient was well able to stand it.

Dr. DOUGLAS VANDERHOOF of Richmond, Va., said that he was pleased to hear Dr. Gordinier's presentation on angina pectoris. The figures in regard to syphilis meant more than mere statements. He thought it could be shown that there was good reason to believe 20 to 25 per cent. of cases were associated with syphilitic cardiovascular disease. Another point was that normal blood pressure, both systolic and diastolic, often existed for years in these cases. In regard to the relation of tobacco to angina pectoris, the speaker said he enjoyed smoking himself and never supposed it did anyone any harm. In one case, however, a Virginia court justice consulted him. He suffered from a very rebellious case of angina pectoris. He had chewed tobacco 53 years. He asked if it did him any harm. Later on the speaker saw the same patient, who volunteered the statement that he had cured himself by leaving off chewing tobacco. He could walk uphill without any pain at all. Another important point was the influence of nitroglycerin in preventing attacks. One surgeon who could not walk a city block without pain in his chest was enabled to carry on his surgical practice. Whenever it was necessary for him to walk he put a nitroglycerin tablet in his mouth. He often said "God bless the man who invented nitroglycerin." It was well to recognize that angina was not a disease, but a syndrome. Typical angina symptoms were seen in pericarditis in children, and it was found with myocardial disease and also in affections of the coronary arteries. It was an interesting condition to watch and treat. Patients might die any moment, yet might survive severe attacks for many years.

Dr. A. ROUSSELL of Philadelphia said that one point of importance brought out was that the classical symptoms of intense anginal pain need not be accepted as the only manifestation. Although no deaths were caused by indigestion, many symptoms were caused by gas, which were the same type of disease. If these symptoms were recognized and treated, patients would live longer. Auscultation and percussion had been overlooked on account of the difficulty of application, but the size of the heart was not the only factor. Brown atrophy, fatty degeneration, showed very little alteration in the size of the heart, therefore the statement that the heart must be enlarged was not correct. Murmur with enlargement would differentiate between organic and inorganic disease.

In regard to the question of rest for sufferers from tuberculosis, in the modern sanatoriums patients could put on 20 to 30 lbs. weight, could have no elevation of temperature, could walk two miles, and yet be getting progressively worse. There should be some mode of differentiating râles showing disintegration of lung tissue, from extrapulmonary râles. The patient losing lung tissue would suddenly break up.

Dr. THOMAS F. REILLY of New York said that in angina there was danger of a patient dying in a second attack and for that reason the family should be warned of the danger. The physician might give a morphine hypodermic and the family would blame him for the death of the patient. Morphine was of more use than nitrites in angina pectoris, but the attacks were often recurrent. In regard to Dr. Zueblin's paper, there were so many conditions in which the patient often had a smaller heart, that one could not lay down a general rule on the subject of cardiac dullness.

Dr. GORDINIER said that with the use of glonoin in arteriosclerosis there was an increase of blood pressure and then a drop. Mackenzie had referred to this temporary rise. The reference to the use of morphine was a wise one. He had had one prominent patient drop dead on the floor after the use of nitrites. It was a wise step to warn the family of the seriousness of the condition, before using morphine.

Dr. MILROY of Omaha said that he felt very sure that the statement in reference to the size of the heart would be challenged. He had qualified the remark. He was speaking in general terms. He did not refer to the men who were experts in diagnosis, but to the vast majority of practitioners who had not expert practice in these cases and could not make such accurate diagnoses. In considering the whole number of cases of organic heart disease, the vast majority of them had cardiac enlargement. He had satisfied himself of the accuracy of his statements by having cases followed up and confirmed by fluoroscopic examination.

Dr. Zueblin said that emphysema might render the findings difficult, but this fact received due attention, and he was having the work confirmed by fluoroscopic *x*-ray plates. The diagnoses were not infallible, and the post mortems showed possibility of errors, but it was desirable to emphasize these changes in the cardiovascular system and to be able to prognosticate them. In regard to Dr. Pottenger's paper, the treatment by rest was well described, and the patient had to realize its importance. The progress of the case should be checked up by *x*-ray findings. As to exercise, the patient's blood pressure should be tested, and if he was doing too much it would be found to fall slightly.

Dr. POTTENGER, in closing, said that putting on weight did not mean anything in a tuberculosis patient. It was the hardest thing to keep them from overeating, because many of them had heard it was beneficial to increase weight. Overeating was detrimental to these patients rather than otherwise.

(*To be continued.*)

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-Fourth Annual Meeting Held at Atlantic City, June 14, 16, and 17, 1919.

THE PRESIDENT, DR. FRANKLIN H. MARTIN OF CHICAGO, IN THE CHAIR.

Toxic Effect of Fibroid Tumors of the Uterus.—Dr. R. R. HUGGINS of Pittsburgh, said that in the absence of other symptoms, it had been suggested that the absorption of toxins incident to the growth of fibroid tumors might account for certain changes in the heart muscles, which undoubtedly occurred in a high percentage of cases. The final proof of this theory remained for the chemist to determine, but in the meantime it was important that clinicians did not overlook certain changes which under other circumstances were commonly accepted as due to toxic products. The frequency of nervous symptoms, oftentimes mild in character but not infrequently severe, the relatively large number of cases of infection of the kidney secondary even to small fibroids, where there could be no question about the absence of pressure upon the ureter or other causes, all pointed strongly in favor of such theories. Since Kasprezig in 1881 first called attention to the frequency of weakness in the cardiac muscles associated with uterine myomata, many articles had been written by gynecologists and surgeons on the subject. It was the consensus of opinion that heart changes were present in from 40 to 50 per cent of the cases. This had been learned from sad experience oftentimes, and there could be no doubt that the severity of the disturbance to heart action in some of these cases during and following operation was secondary only to that which occurred in thyroid disease. In earlier years paralysis of the heart was given as the cause of death after autopsy revealed no other excuse. Fleck made a study of 325 cases and found either functional or organic changes in 40.8 per cent. In every instance where an autopsy was made definite cardiac changes were found, such as fatty degeneration, brown atrophy, etc. He did not believe the heart changes were due to loss of blood because out of 133 cases in which there had been no hemorrhage cardiac changes were present in 34.6 per cent. Winter insisted that an etiological relationship between myoma and heart disease had not been proven, and that the heart was influenced only by the secondary anemia due to the hemorrhage which was caused by the myoma. He admitted, however, that 60 per cent. of a series of 266 cases, where a study of the heart was minutely made, showed a myoma heart. Such change in the heart muscle was not infrequently recognized by men of large experience.

The Origin of the Intrapelvic Treatment of the Stump After Supravaginal Hysterectomy for Fibroid Tumor of the Uterus.—Dr. J. RIDDLE GOFFE of New York referred to the hopeless attitude of the profession in the latter part of the century toward the surgical treatment of fibroid tumors. He said that all surgical procedures had been improved by the introduction of antiseptic and aseptic methods. Fibroids had demanded an improved method of procedure, a new technique. He spoke of who discovered it, how it was brought to its present high state of perfection, and the part played by himself in its achievements. On May 29, 1898, he did his first operation at St. Elizabeth's Hospital by an original method, which, he said, was frequently incorrectly credited in the literature to Baer of Philadelphia. This method embraced new untried features and met all the requirements of a masterful procedure. First and foremost, it solved the problem of dropping the pedicle and closing the abdominal incision without drainage. Second, it covered all raw surfaces. Third, it fastened the infundibulopelvic and round ligaments to the stump, thus giving support to the pelvic diaphragm. Fourth, it restored the organs to their normal position and relations in the pelvis, where they could functionate normally, disposing of the traumatic tissue with the nicety of a plastic operation. All these things he pointed out in his first paper describing the operation, which was published in the *American Journal of Obstetrics and Diseases of Women and Children*, for April, 1890.

Uterine Myomata with Some of the Complications Seen in Practice.—Dr. EDWARD E. MONTGOMERY of Philadelphia said that myomata were prone to complications which make the diagnosis and prognosis difficult. Among the complications were nutritive disturbances. The enlarged and irregularly developed uterus, to accommodate itself to the contour of the pelvis, rotated on its vertical axis, obstructing the return of blood through the veins, while the more rigid arteries continued to deliver the current. Edema and partial or complete necrosis might follow. Pregnancy might lead to such rapid growth of the tumor as to necessitate immediate resort to surgery. A subserous growth with pregnancy might be pressed between developing uterus and the bony or parietal wall, arresting its circulation. On the right side, it simulated appendicitis. In one case it caused abortion and subsequently necessitated hysterectomy. Myomata encroaching on the uterine canal increased the danger of infection. Tubal infection, ovarian hematoma, pyuria, and sacculated kidney were sometimes among the complications.

A Study of Frozen Sections of the Pelvis with a Description of an Operation for Pelvic Prolapse.—Dr. ALFRED BAKER SPALDING of San Francisco stated that the pelvis of a 32-year-old woman, nullipara, was cut

by frozen section into four segments. The surfaces of the segments were photographed and the pelvic fascia outlined. The uterus could be seen hung as in a swing by the paracervical tissue which was intimately attached to the pelvic fascia, the arcus tendineus of which gave strong support to the bladder, vagina, and rectum. The levator ani muscle and fascia supported from below and brought toward the symphysis the lower part of the vagina and rectum. The operation which he described had been done only during the past few months, and the immediate results had been very satisfactory. The operation consisted in dissecting free the fascia in the anterior vaginal wall to the arcus tendineus and overlapping as described by Rawls. Amputation of the cervix was performed and on either side of the cervix two deep sutures were placed to control hemorrhage. The peritoneum was open below the bladder and a subtotal vaginal hysterectomy was done, attaching the cervical stump to the sacro-uterine and several broad ligaments. The round ligaments were drawn through the cervical canal and sutured on the vaginal surface. With rectal prolapse the rectum was supported by operations described heretofore by Ward, Studdiford, and others. Emphasis was laid on the value of preserving the paracervical tissue by means of a subtotal vaginal hysterectomy and of supporting the cervix by drawing the round ligaments through the cervical canal.

The Hairpin as a Foreign Body in the Female Bladder.—Dr. WALTER P. MANTON of Detroit gave a brief history of the development of the hairpin, its abuse, and its comparative frequency as a foreign body introduced in the female bladder, and reported an unusual case under observation for a period of more than ten years. He also gave a report of the autopsy and pathological findings.

A Unique Diffuse Uterine Tumor, Really an Adenomyoma with Stroma but No Glands; Menstruation, After Complete Hysterectomy, Due to Uterine Mucosa in the Remaining Ovary.—Dr. DE WITT B. CASLER of Baltimore reported a case in which a panhysterectomy and a right salpingo-oophorectomy were done for a supposed myoma of the uterus following a metrorrhagia of one year, in a patient, 39 years of age. The gross specimen was found to have a large reddish polyp filling the cavity, while the walls of the uterus had a peculiar appearance, small, comedo-like masses standing out prominently above the cut surface on pressure. Sections showed an almost total absence of uterine gland but finger-like masses of interglandular stroma, dividing the uterine muscle into a fine meshwork, were seen extending as far as the peritoneal surface. Following this was a history of regular menstruation lasting one day each month for four years, when at a second operation a cystic tumor of the left ovary was removed. This was found to contain many reddish polypi resembling in appearance the uterine specimen previously removed and to be made up almost entirely of uterine tissue, glands, stroma, and normal appearing uterine mucous membrane.

Elective Cesarean Section.—Dr. EDWARD P. DAVIS of Philadelphia stated that enlargement of indications for cesarean section made it necessary to define clearly the indications, especially in the field of elective operation. Elective operation was justifiable only when conditions present were such that any other procedure would be much more dangerous for mother and child. To make this decision, extensive experience in obstetrics was necessary. Elective section could not be a frequent operation. It was justified in physiological incompetence for labor, in some abnormal positions and presentations, in cases of repeated overgrowth of the child, and in cases where previous labors had been dangerous.

The Treatment of Certain Cases of Placenta Previa by Conservative Measures.—Dr. GEORGE W. KOSMAK of New York said that since the perfection in methods of performing the abdominal cesarean section, this had been widely advocated as one of the most satisfactory methods of relief in this condition and in a limited class of cases it was undoubtedly of value. The older procedure involving the Braxton-Hicks version with perforation of the placenta and the use of the fetal thigh as a tampon hardly seemed a fair procedure in view of the certainties attending the classical cesarean section, and was becoming generally discarded except as a measure of emergency. The primary danger to the mother from hemorrhage and shock and the secondary risks from sepsis and embolism had been the deciding factors in adopting any method of treatment and all deliveries by the vaginal route were overshadowed by these possibilities. In cases presenting a rigid and only slightly dilated cervix in a primipara and the probability of a central placenta previa with the child at or near term and still in good condition, because the amount of bleeding had not been extreme, there was no question but what the abdominal cesarean section offered the best method of delivery for both mother and fetus. But it would be found that the large majority of cases were outside of this group; that we were not dealing with central implantations of the placenta but those in which only a portion of this organ impinged upon the region of the internal os or the lower uterine segment, so that hemorrhage of any extent resulted only after the cervix had become thoroughly softened and was dilating. Nevertheless, even in this group the amount of bleeding might be sudden and excessive, especially as the lower uterine segment in multiparæ, in whom we most often found this abnormality, was thoroughly softened and separated easily from the placenta. As the first consideration in any given case was to stop the hemorrhage, the vaginal pack might seem to offer a ready solution, especially as its application was usually an emergency one. Unfortunately we found that in many cases of patients admitted to our hospitals in whom this procedure had been resorted to, the blood saturated the substance of the gauze or absorbent cotton ordinarily employed and allowed for the collection of large clots above the packing without control of the hemorrhage. The pack, moreover, acted as a stimulus to uterine contractions, and as the membranes were often unruptured the presenting part was not satisfactorily forced down against the bleeding area in order that it might act as a check on the same. The use of the elastic bag in place of the gauze pack had been widely advocated and unquestionably good results had followed its employment. The usual procedure directed the insertion of the bag through the ruptured bag of membranes or through the mass of the placenta, with or without traction on the same to insure compression. In criticising the mechanics of this procedure attention must be called to the fact that such compression of the bleeding area in the lower uterine segment was necessarily indirect, because the soft placental mass remained interposed between the bag and the uterine wall and more or less continuous bleeding, even if only slight, was usually present. In the attempt to introduce the bag it had been his experience that considerable bleeding might result from this effort because of the undue placental separation brought about by the same. He also found that unless strong labor pains were induced, the bag was not firmly held against the placenta unless traction was applied, and if the latter was not carefully guarded a sudden laceration or rupture of the lower uterine segment might take place. In view of the shortcomings and the desire for a possibly more satisfactory method of treatment along these lines, what modification of such method could be advocated as a substitute? It must be borne in mind that it was essential to bring about gradual dilatation of the cervix without laceration, to reduce the possibility of hemorrhage as much as possible, to avoid septic infection and, of course, to deliver a living child. Control of the hemorrhage during the process of dilatation remained the important indication, and this he believed could be more effectively made by the extraovular introduction of the bag than by any other means. His attention was first called to this method by its description in the textbook brought out by Dr. E. B. Cragin shortly before his death. In reading this description he was struck by the good results which Dr. Cragin claimed for the method, and while at first skeptical of its value, he soon afterwards began to employ the same. Although not an infallible procedure, he believed that a thorough trial would convince every one of its practicability and value in the majority of cases. It was for this reason that he had ventured a preliminary report on the procedure in the expectation of publishing a more complete study at a later date. He had become impressed with the fact that as an emergency measure it was much superior to the intraovular

introduction of the bag because less harm was done by hospital interns, for example, than if the perforation of the placenta was a Braxton-Hicks version or intraovular introduction of the bag was carried out. As soon as a diagnosis was made, no further manipulations were necessary in attempting to enter the amniotic cavity, and the bag might be introduced through the os alone very much more quickly. A résumé of the cases of placenta previa, taken from the records of the New York Lying-In Hospital from June, 1904, to December, 31, 1918, showed a total of 534 cases. Among them there were recorded 75 deaths of mothers (14 per cent.) and 105 deaths of children after delivery. A total of 223 still-births was recorded, making a total fetal mortality of 328, or 62 per cent. These cases were treated by a variety of methods other than the extraovular bag insertion. While this was rather an alarming proportion of both maternity and fetal deaths, the fact must be borne in mind that a great many of these cases were sent in by outside physicians after various methods of treatment had been employed, and usually considerable hemorrhage had resulted. The personal cases previously referred to were but three examples of about ten consecutive cases of placenta previa, which he had observed with the extraovular bag method. Although insufficient in number to permit of general conclusions, they had impressed him with the value of the procedure, and in calling attention to a method which had not been very extensively used and was purely obstetrical in character, it was with the hope that it might be given a more extensive trial by others. It seemed particularly adapted to multiparæ with moderately softened cervices, was readily applied, did not of itself cause additional bleeding, reduced the necessity for extensive manipulations, was free from shock, and safer and more efficient for emergency use.

The Pelvic Articulations During Pregnancy, Labor, and the Puerperium; an X-ray Study.—Dr. FRANK W. LYNCH of San Francisco stated that his study had developed from observations in an effort to use the *x*-ray for diagnostic purposes in gynecology and obstetrics, as well as from interest in a case of rupture of the symphysis during labor, which came under his care three years later with marked symptoms in her second pregnancy; and by the great number of sacroiliac slips seen in his service in spite of proper correcting. Since he was not aware of a similar series of *x*-ray studies of pelvic articulations, he was presenting some of his cases. It was difficult to present conclusions because of the constant chance of error in deductions from the *x*-ray plate. Only one woman studied had had marked widening of the symphysis during pregnancy, with a return to normal limits when seen 15 months later. It appeared, however, as if the widening of the sacrosciatic spaces occurred very frequently.

Lantern Slide Demonstration of an Early Human Ovum in Situ in the Act of Aborting.—Dr. J. WHITRIDGE WILLIAMS of Baltimore said that the pregnancy was found in a uterus removed on account of multiple myomata forty-two days after the last period, and fourteen days after the nonoccurrence of the next expected period. Instead of furnishing an early example of normal implantation, the ovum was found to be abnormal, some of the villi were the seat of hydatidiform change, and all traces of an embryo were lacking. The decidua capsularis was ruptured and the egg was in the act of being extruded. The demonstration of serial sections showed the mechanism by which early abortions occurred.

Premature Separation of the Normally Implanted Placenta.—Dr. ARTHUR H. MORSE of New Haven, Conn., stated that ligation of the uterine veins in pregnant rabbits reproduced lesions in the uterus identical with those in women suffering from premature separation of the placenta. Similar lesions in rabbits would result from constriction of the vessels when the uterine horn was rotated. Premature separation of the placenta in women also probably depended on an acute disturbance of the uterine circulation.

The Nutrition of the Fetus.—Dr. J. MORRIS SLEMONS of New Haven, Conn., stated that the nutrition of the fetus involved two factors, namely, the peculiar activity of its own organs and the supply of food they received. The first was the more fascinating and also the more difficult of study, because the isolation of the fetus baffled the most ingenious experimenters. In the absence of specific knowledge regarding the intermediary fetal metabolism, our nearest approach to the facts was to accept its analogy with adult nutritional processes; and yet in doing so one was conscious of not being logical, for the unusual prominence of certain organs, as the thymus gland, intimated the existence of radical differences between the metabolism of the immature organism and that of the adult. The second factor in the nutrition of the fetus dealing with the origin and the variety of materials incorporated in its body had been brought within range of direct observation, and certain familiar deductions therefrom had a practical application. There was no diet specifically adapted to the state of pregnancy; the prospective mother might exercise the same freedom as any one else in the selection of food. She should select what would agree with her and avoid that which she could not digest and assimilate. Personal experience in the main must guide every one as to what to eat, and most women followed the dictates of appetite after they became pregnant as safely as they did before. In a practical sense the quantity of the mother's food was more influential than its quality. Popular opinion held that during pregnancy the mother "should eat for two." This doctrine was erroneous. A diet which had previously been ample would likewise be sufficient throughout pregnancy. And, it was not unimportant to emphasize this view, which had the unqualified support of painstaking, scientific investigations, because overeating during pregnancy was much more likely to provoke discomfort than insufficient nourishment. On the other hand, there could be no justification for measures intended to restrict the growth of the fetus, for when rigidly carried out they tended to weaken the mother. She might be careful, in other words, to avoid overgrowth of the fetus, but should not adopt a diet so limited as to interfere with normal development. So long as her health was properly maintained, no thought might be given as to what the size of the fetus was likely to be. At present, provided the physician determined by a thorough, preliminary examination the existence of any disproportion between the size of the fetus and the capacity of the mother's pelvis, he was qualified to decide what the appropriate treatment should be in order to bring pregnancy to a successful termination.

(*To be continued.*)

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held May 26, 1919.

THE PRESIDENT, DR. CHARLES H. PECK, IN THE CHAIR.

Digest of the Federal and State Narcotic Drug Laws.—GEORGE W. WHITESIDE, Esq., Counsel for the Medical Society of the State of New York, presented this communication. He said, in part, that the Department of Narcotic Drug Control was created in 1918 by an act to amend the Public Health Law, so as to provide for the regulation and control of the sale, prescribing, dispensing, dealing, and distribution of cocaine and opium and its derivatives and making an appropriation thereof. The act provided that the department be administered by a commissioner at $6,000 a year, three deputy commissioners at $3,500 a year, and the necessary office force. The commissioner was empowered under the act to make rules, regulations, rulings, and decisions which in his judgment were necessary to effectuate or supplement the purposes of the act or to interpret its provisions; to provide the necessary procedure to secure the enforcement of the provisions of the act, and it specifically provided that the rules, regulations and decisions of the department, until modified or rescinded, were to have all the force and effect of statute. The commissioner was given the authority after a reasonable notice and opportunity to be heard of revoking any certificate of authority issued by the Department of Narcotic Drug

Control and of cancelling or withholding official blanks issued or applied for. He and each of his deputies was given the authority to administer oaths, compel the attendance of witnesses, production of books and papers, to take proof and testimony concerning all matters within the jurisdiction of the department, and that in such connection communication made to a physician should be deemed confidential. The duty of the commission was to obtain data and information relative to the extent of drug addiction and the means by which it could be controlled, reduced, or eliminated, and the means and methods used in this treatment. This was the fundamental purpose of this statute. He had the power to inspect and examine any hospital, sanatorium, institution, or place in which persons were treated for drug addiction, and must annually report to the Legislature with such recommendations as he might deem warranted. The act expressly forbid the unauthorized possession, sale, distribution, administration, or dispensation of cocaine or opium or its derivatives and declared any of these acts to be dangerous to the public health and a menace to the public welfare. It provided that manufacturers, wholesalers, apothecaries, physicians, dentists, veterinarians, or private hospitals, sanatoriums, or institutions maintained or conducted in whole or in part for the treatment of disability or disease or inebriety or drug addiction, should register with the Department of Narcotic Drug Control the name or style, place, residence and place or places where such business was carried on and receive from the department a certificate authorizing the carrying on of such business. The speaker read that part of the law showing how possession of these drugs was to be obtained upon official order blanks and explained that the orders must be made in triplicate, upon serially numbered blanks issued by the department. Subject to the rules, regulations, rulings, and decisions of the department preparations and remedies which were not otherwise prohibited by law might be manufactured, sold, dispensed, or be in the possession of a person, if they did not contain more than the lawful quantity of opium or its derivatives; liniments, ointments, and other preparations containing such drugs which were prepared and suitable for external use only, could be sold, dispensed, or possessed as medicines provided they were not for the purpose of evading the intention and purposes of this act. The lawful quantities referred to were as follows: Opium, 2 grains; codeine, 1 grain; morphine, ¼ grain; heroin, ⅛ grain per fluid ounce or avordupois ounce. Apothecaries might, upon prescriptions written on *unofficial* prescription blanks, signed, and containing the office address of the physician, the name, age, and address of the person for whom the drug was intended, and the date when issued, dispense cocaine, or opium or its derivatives, provided the prescription did not contain more than five grains of cocaine, or more than thirty grains of opium, or more than six grains of codeine, or more than four grains of morphine, or more than two grains of heroine. They might fill prescriptions containing an excess of the quantities stated if it was set forth upon the prescription that it was to be used in the treatment of a surgical case or a disease other than drug addiction. Apothecaries might fill prescriptions in writing signed by a physician and containing his office address and the name, age, and address of the person for whom it was intended and the date when issued, within four days from such date, for cocaine or opium or its derivatives within or in excess of the quantities mentioned, if such prescription was written upon a serially numbered official prescription blank delivered to him in duplicate. One of the duplicates he must keep in a separate file for a period of two years and within twenty-four hours mail the other duplicate to the department. Such prescription must not be refilled. A physician might in the course of the legitimate practice in good faith of his profession and for the purpose of relieving or preventing pain or suffering on the part of a patient or to effect a cure, administer, prescribe, or dispense cocaine, or opium, or its derivatives as follows: A physician might upon unofficial prescription blanks issue prescriptions which did not contain more than five grains of cocaine, or more than thirty grains of opium, or more than six grains of codeine, or more than four grains of morphine, or more than two grains of heroine. He might also upon unofficial blanks issue prescriptions for such quantity of these drugs in excess of the quantities mentioned as might reasonably be required in the treatment of a surgical case or a disease other than drug addiction, provided this fact was set forth upon the prescription. The above took care of the doctor who was not treating drug addiction. Each other prescription for any such drugs must be written upon a serially numbered official blank in triplicate to be procured from the Department of Narcotic Drug Control signed by the physician and containing, in legible English or Latin, the name and amount of the drug prescribed, the name, age, and address of the person for whom and the date when the prescription was issued. In these instances the physician must issue an original and a duplicate prescription for delivery to the apothecary and retain the other copy on file for a period of two years. Physicians might administer or dispense to the patients whom they were treating not to exceed two grains of cocaine, or two grains of morphine, or one-fourth of a grain of heroin; he might dispense to be taken in his absence by a patient whom he was treating not to exceed fifteen grains of opium and three grains of morphine, or one-fourth of a grain of heroine. If a physician administered or dispensed drugs otherwise a complete record of the prescription together with the name, age, address of the patient, and the date must be kept and a copy sent to the Department of Narcotic Drug Control within twenty-four hours. Apothecaries and physicians who dispensed cocaine or opium or its derivatives where records were required to be kept must affix to the container of the drug a label stating in legible English the name and address of the physician or apothecary prescribing, and the date when, the name, and address of the person for whom and the name and quantity of the drug in the container. The law in reference to private hospitals and institutions stated that unless a certificate of authority should first have been procured from the Department of Narcotic Drug Control, and so long as such certificate remained unrevoked, cocaine or opium or its derivatives should not be administered to any person treated for inebriety or drug addiction in a private hospital, sanitorium, institution, or place maintained or conducted in whole or in part for the treatment of inebriety or drug addiction. The law in reference to the keeping of records stated that physicians were required to keep records of all cocaine or opium or its derivatives purchased or received by them, which record should contain the date of each purchase or receipt, the name and address of each person from whom, and the name and quantity of each drug purchased or received. They must keep records of the gross amount of drugs administered by them to patients in quantities not exceeding the lawful quantity. They must also keep records of drugs otherwise dispensed by them, which records should contain the date when, the name, and the address of the persons to whom, and the name and amount of each such drug so dispensed. Physicians, as required, should make and mail to the department reports setting forth such of the information and reports as the commissioner might require, together with the amount of such drugs on hand on the date of such report. The law also provided that hospitals, sanitoriums, and other institutions should keep records similar to those required of physicians. Each prescription written upon an official blank and each other record, except prescriptions required to be kept by the apothecary, must be contained in books, the leaves of which should be permanently bound together, and these records must be kept in a place easily accessible and accessible to the Department of Narcotic Drug Control for a period of at least two years. Mr. Whiteside, after outlining the method of procedure for the commitment, treatment and discharge of drug addicts, stated that the law provided that any public hospital, sanatorium, or institution might accept as a charity patient any person voluntarily applying for treatment for drug addiction and if the applicant signed a statement that he was suffering from drug addiction and desired treatment, in the same manner and subject to the same rules and restrictions as if committed by a magistrate, then the hospital might receive such person without formal commitment. However the effect was the same as though he were formally committed and he was subject to discharge when suffi-

ciently treated or for any other reason deemed adequate. The commissioner or any local health board had the authority on a similar application to place the applicant in any hospital receiving such patients at public expense. The provision of the section should not restrict the right of any hospital, sanitorium, or institution to accept and treat patients for drug addiction at their expense, but not at public expense. If it was found that any physician, dentist, veterinarian, pharmacist, druggist, or registered nurse was addicted to the use of any habit forming drug or drugs, his or her license might be revoked or suspended after giving the licensee notice and opportunity to be heard. If the licensee recovered a rehearing might be granted and the license might be reissued. A violation of any of the provisions of the act constituted a misdemeanor.

Mr. Whiteside then discussed the Federal acts bearing on the subject. Under the Harrison law, enacted in 1914, it was important for the physician to remember that he must be registered under the act and must keep records of all drugs dispensed or distributed, showing the amount dispensed or distributed, the date, name, and address of the patient to whom such drugs were dispensed or distributed, except such drugs as might be dispensed or distributed to a patient upon whom a physician, dentist or veterinarian was personally attending. These records were to be kept for a period of two years. Prescriptions must be dated as of the day on which they were signed, and they must be signed by the physician, dentist, or veterinarian who issued them, and the dealer to whom the consumer presented the prescription must retain it for a period of two years from the date on which the prescription was filled. The law with reference to sworn statements was that any person who had registered under the provisions of the act should, if required by the collector of the district, render true and correct statement or return verified by affidavit setting forth the quantity of the drugs received by him in his district during such period preceding the demand of the collector not exceeding three months, as the collector might fix and determine, the names of the persons from whom the drugs were received, the quantities in each instance received from each such persons and the date when received.

U. S. Court Decisions on the Narcotic Law.—BENJAMIN A. MATTHEWS, Esq., Assistant U. S. District Attorney, presented this paper, in which he confined himself to the definitions of certain phrases which occurred in the Harrison Law that affected the practice of medicine and to decisions rendered by the Supreme Court in certain cases coming under this law. The phrases upon which decisons had been rendered were "Personally attend," "Prescription," "Prescribe." The decision on the phrase "Personally attend" was rendered in the case of Dr. Nathan Tucker against Williamson, the Collector of Internal Revenue of Ohio, and placed a more restricted meaning on personal attendance than the courts had placed on medical attendance, it being held that to constitute the latter it was not requisite that the physician should attend the patient at his home and that an attendance at his office was sufficient, while the phrase in its more restricted sense implied that personal investigation preceded and personal supervision accompanied the prescribing. The decision in regard to the word "prescription" was rendered about a year and a half ago in connection with a case against some men who claimed to be doctors and were using slips of paper with ℞ written in the upper left hand corner and between that and their names they put down various amounts of cocaine or heroin. He found that the courts had considered this word a great many times, and it had come to have a very definite meaning in law, being defined "To write or to give medical directions; to indicate remedies." It would make no difference whether the direction was given by the person in charge of the patient himself or by another person, even though he was a licensed physician engaged by and under the control and direction of the person in charge in that particular. Other definitions were quoted to show that the term might have a broader significance than merely the prescription of medicines, since it might be found after examining the patient that he did not need medicine, but needed different food, different air, or different employment, etc. He did not attempt to define "professional practice," because there were a number of cases pending in the Southern District of New York wherein the courts would have to define it a little more definitely than it had yet been defined. He was going to wait for them to define it. The Harrison Law, as had been stated, was only an internal revenue tax law. The only power Congress had was to pass a law and to collect excises. It was an excise law affecting doctors, druggists, and manufacturers of narcotics. An old objection raised in connection with this law was that Congress had no right to pass such a law in relation to the matter of narcotics. The State, it was contended, could do it, but not Congress. This argument was pressed very vigorously and almost successfully, the decision being five to four, the Chief Justice being among the dissenters in the Supreme Court. That went to the Supreme Court in two cases which were argued on the same day. One of these was the case of the United States v. Doremus. Doremus had been charged with distributing to a man named Aleris 500 one-sixth grain tablets of heroin. The indictment charged that he gave those to Ameris, not in the course of his professional practice, but merely to satisfy the craving of Ameris for the drug. The lower court ruled that the law was unconstitutional. The case was then carried to the Supreme Court and Congress was held to the court to have that power, because the regulation in the statute permitting the sale and outlet of it were directly related to the raising of revenue. The speaker read the text of this decision in full. On the same day the Supreme Court also decided the case of Webb against the United States. Webb was a physician in Tennessee, who was indicted with a man named Golfbaum, as druggist, and was convicted with the druggist of writing and filling prescriptions for drug addicts. The case went to the Circuit Court of Appeals and by that court certified to the Supreme Court. Three questions were propounded by the lower court to the Supreme Court, and the Supreme Court in its decision merely answered those questions. The first question was: "Does the first sentence of Section 2 of the Harrison Act prohibit retail sales of morphine by druggists to persons who have no physician's prescription, who have no order blanks therefore, and who cannot obtain an order blank because not of the class to which such blanks are allowed to be issued?" The answer was, "Yes, it did so prohibit." The second question was, "If the answer to question one is in the affirmative, does this construction make unconstitutional the prohibition of such sale?" The answer to that question was "No; that it did not." The third question was, "If a practising and registered physician issues an order for morphine to an habitual user thereof, the order not being issued by him in the course of professional treatment in the attempted cure of the habit, but being issued for the purpose of providing the user with morphine sufficient to keep him comfortable by maintaining his customary use, is such an order a physician's prescription under exception (*b*) of Section 2?" The answer was "No." That question and that answer were of more interest to the medical profession than all else that had been written on this subject. This was the Supreme Court speaking and it was final and authoritative until Congress or the court itself changed the rule. Mr. Matthews related a somewhat similar case which he himself tried against two druggists and a doctor in New York City, and also an interesting case which was decided by the State Board of Health of Rhode Island. This decision was printed by Dr. Copeland in his Bulletin a few days ago. The case was Noop v. State Board of Health, 103, Atlantic 904, 4q R. I. This case arose on appeal from the decision of the State Board of Health and the order of the said Board revoking the license of the appellant to practice medicine. Twelve witnesses were produced by the State who testified in regard to the procedure by which numerous prescriptions for morphine and cocaine were secured from and furnished by the appellant. The evidence quoted showed that the appellant had been guilty of gross unprofessional conduct and of conduct making him an unfit person to practice medicine in that State. The finding of the State Board of Health revoking the certificate of appellant authorizing him to practice medicine and surgery in Rhode Island was affirmed.

Rules and Regulations of the New York Department

of Narcotic Drug Control.—Walter R. Herrick, Esq., State Commissioner of Narcotic Drugs, spoke on this subject. He stated that though he had been in office but a short time he had discovered that there was considerable objection to the statute which aimed to control the narcotic drug evil. He knew that the physicians had not been instrumental in putting it there and he had not put it through, but the law was there and as a consequence it must be administered and carried into effect, and there was no way of evading this responsibility. The problem now was so to adminster and carry into effect the law that it would not interfere with the doctor or druggist who was honestly practising his profession. These need not fear. The only one who should be afraid was the dishonest man, and in seeking to eliminate him he believed he had the cooperation of all honest physicians; the others he would look after in due time. He understood from several remarks he had heard earlier in the evening that objections had been raised to the registration of addicts. As a matter of fact, a system of registration was in effect at the present time, and he had heard no objection to registration on the part of the addicts. The only objection that had reached him was that voiced by the medical profession. The fear of identification seemed to have been only one of anticipation and was based on no real objection. The law was just as Mr. Whiteside had stated. It aimed to control the manufacture, sale and distribution of narcotic drugs, and if it was carried out as planned it would control the whole situation in the course of time. If the law was carried out it would mean the absolute eradication of the use of narcotic drugs by people who had become addicted to their use. In administering the law it was his object to reach both the distributor and the consumer of the drug. He had concluded that the way to cure drug addiction (and this was not the conclusion of a layman) was by the reduction of the drug, but one could not carry out the reduction treatment unless the addict was properly cared for after the reduction treatment was completed. Doctors and others agree that after the drug has been eliminated if the addict is allowed to go free he returns to the use of the drug. That meant that they must have control of the addict and to do this he must be placed in an institution, just as we now place patients in the hospitals for the insane, and he must be kept there until the doctor who was attending him said he was cured. That was going to mean a large expense to the State, but it must be remembered that this was a serious condition with which we had to contend. The doctors must realize that we had the most populous state in the Union and where there was congestion of population there would be a great increase in drug addiction. He did not want and he did not believe anyone wanted New York to be the banner state in the Union for drug addiction. The only way to prevent that situation was to have the medical profession cooperate with the Federal, State, and municipal authorities and to take hold and help to control legislation. He not only expected the medical profession to back up the Narcotic Drug Commission, but to back it up with every bit of energy it could exert.

The Narcotic Addict in Relation to the Health Department.—Dr. Royal S. Copeland said he sympathized with the medical profession in the difficulties and complications that were created by the Narcotic Drug law. He was not at all surprised that there was a feeling of resentment on the part of physicians when they undertook to cope with the intricacies of the methods that had been adopted for the control of the drug evil. Most physicians did not care to treat drug addiction, so that as the situation now stood we had a high incidence of a disease which the profession would not treat, and that while it was not a function of the Health Department to treat disease there seemed under the circumstances no other course but for the Health Department to deal with the problem. There was no question but that it was a very real problem. As a result of the recent raid conducted by the Collector of Internal Revenue and the Police Department fifteen physicians and druggists were taken to court for violating the Harrison Law. Thus many addicts were deprived of their customary source of supply and the Health Department found itself with 2,000 patients on its hands. Any person who would come down to the clinic at 145 Worth Street where these addicts were being treated would see such absolute wrecks of humanity as he had never gazed on before and would no longer question the wisdom of the Health Department in caring for them. Commissioner Copeland quoted figures to show the great increase in the amount of habit forming drugs that had been sold during the past winter, and said that the report of the Federal Drug Committee which was investigating the question of drug addiction in the United States estimated that there were at least one million addicts and possibly three or four million. According to this estimate there were as many as 60,000 addicts in New York City. It was well known that drug addiction increased with the concentration of population and the probability was that there were at least 100,000 addicts in this city. During the year 1917, 470,000 pounds of opium were imported into this country, an allowance of 33 grains per capita. There was no other civilized country in which the per capita allowance was more than 3½ grains. Such figures as these should indicate to the medical profession the importance of the problem with which they had to deal. Commissioner Copeland assured Mr. Herrick that in his endeavor to have registration of addicts he would have the hearty cooperation of the Health Department. There were at present four sources of supply from which narcotic drugs were obtained, namely, the Health Department, the honest doctor, the dishonest doctor, and the bootlegger. They had not been able thus far to control the dishonest doctor and the bootlegger but they were going to be able to do so through the Federal authorities and the Police Department. In order to show the necessity for registration and identification, Commissioner Copeland described how it was possible for an addict to get say 15 grains of his drug from the Health Department and then go to one or more physicians and without telling that he was being treated by the Health Department get more of the drug. He thought that if the doctor would stop to consider all the subterfuges to which an addict would resort to get his drug they would realize that they were confronted by a situation which demanded the cordial support of the medical profession. He knew some of the members of the society were opposed to registration, but he did not see how the evil could be controlled without it. Mr. Herrick and a committee from the Medical Society of the County of New York had met and discussed the matter and it was explained that in the plan for registration it was not intended in any way to interfere with the legitimate prescription of narcotics, as for instance in cases of incurable cancer. In such cases registration of the patient was not required; all the doctor had to do was to write on the prescription "incurable cancer." The only person to be registered was the drug addict pure and simple. In order to get their drug they would have to have their identification card. Those who were practising legitimate medicine need have no fear that they would be imposed upon. It was well to remember that even those addicts in the higher walks of life, when it came to getting the drugs to which they were addicted, would lie. Dr. Copeland said that as long as he was in office he was going to try to clean up New York of every disease, whether it was venereal disease, smallpox, influenza, or drug addiction. He felt that it was right that the Medical Society of New York should be asked to lend its cooperation in endeavoring to wipe out drug addiction.

Dr. Peck assured Dr. Copeland that he could count on the support of the society in this work.

The Law and the Narcotic Addict.—Hon. Cornelius Collins, Justice of the Court of Special Sessions, stated that he was one of the men who had been instrumental in drafting the narcotic drug law. He realized that there was a good deal of contention as to the advisability of this legislation, but the extent of drug addiction had made such legislation necessary. Drug addiction came over this country very much like an epidemic in the suddenness with which it appeared. It was first made manifest in the court room, where they found that many arraigned for criminal offenses were drug addicts. Some appeared in the court room under the influence of a drug, and others were under the in-

fluence of a drug when they committed the crime with which they were charged. When they first began to work on the problem of drug addiction they did not consider heroin a habit-forming drug, but they had learned that it was the worst of the habit-forming drugs. After the Boylan and Harrison laws went into effect addicts began to come to the hospitals and to the medical profession in great numbers to be treated. They had felt that the people would become hysterical when these laws went into effect, hence the law of 1915 was so constituted that commitment could be had without sentence, and immediately after this the hospitals were overrun. The medical profession and the hospitals did not want to treat drug addicts, so the bootleggers, rats, and runners began to distribute these drugs. Many ex-convicts also engaged in the traffic. In spite of the Harrison law drug addiction continued to increase and this was because there was a loophole in the Harrison law, and that was that there was nothing to prevent anyone from purchasing these drugs in Canada or Mexico. They were brought into this country mixed in other substances, as in sugar of milk, so that the person who bought them was being defrauded. During the year 1914 there came into the courts of New York 1,415 drug addicts; in 1915 there were 1,503; in 1916, 1,626; in 1917, 1,283; in 1918, 436, and during the last four months only 125. These cases were not all brought in for violations of the narcotic drug law. Only about one-half were brough in for drug addiction, while the remainder were brought in for other offenses, and the court has discovered that they were addicts. While the law of 1918 was very extreme, it was not drawn up with the intention of annoying the medical profession. It was based on the good faith of the medical profession and he defined good faith. He was instrumental in drafting that part of the law himself. In the Whitney bill the doctors were given the right to treat drug addiction and were encouraged to do so. After this there was a decided fall in the number of addicts coming into the courts, and there was a disappearance of the illicit peddlers. It would seem from the decrease in the number of addicts seen thus far this year that the law was having a good effect. The evil that still existed was that a few members of the medical profession were disgracing their profession by illicitly giving out drugs. The recent raids were made in order to reach these doctors and to expose them. Under the last statute the Commissioner of Narcotic Drugs had the right to take steps to meet any situation that might arise and he was the man to whom the doctors would have to take their complaints. At one time those who were interested in this legislation pled with the medical profession to treat these cases of drug addiction, but they had now come to realize that the drug addicts needed special study and should be treated in an institution. This, of course, was impracticable at the present time when, according to conservative estimates, there were 60,000 drug addicts in the city. Senator Herrick could do a great deal of good if he came to their aid and got data with reference to the extent of the drug evil in New York and in the metropolitan district, and this was one of the duties of his office as set forth in the statute. The number of addicts who had received drugs illegitimately during the past few months was negligible. The most important thing at the present time was to know with some degree of certainty what we were talking about, and in the procuring of this data the official blank was the first step. A second point to be emphasized was the phrase "good faith" of the profession. The speaker was the originator of that part of the statute which referred to the good faith of the profession, and he had defined "good faith" as following and acting in accordance with the recognized standard of the medical profession which had for its purpose the cure of disease. The law left a great deal to the professional judgment of the physician, and whenever it could be shown that a man was acting in accordance with his professional judgment he was in the right according to the decision of the court. The fact had also been taken into consideration that a patient might not necessarily be treated for the purpose of obtaining a cure, but that the treatment might be from the standpoint of relieving human suffering and pain. There might be emergencies in which it was necessary to prescribe a narcotic drug with no idea of cure, as when an addict, deprived of his drug for a time, became so weak and upset that he fell to the floor of the courtroom. The law must be interpreted to meet such emergencies. He believed that registration could accomplish its purpose and he could see no harm from an addict having a card of identification in his possession, since no one need know about it except his doctor and himself. He thought Dr. Copeland was to be complimented on the way in which he had handled the problem. The fact that one saw a large number of addicts at the clinic downtown did not mean that the number of addicts had increased recently, it only meant that the raids had exposed the extent of the evil. There was a class of addicts who had become such in consequence of injury or illness during which narcotics had been prescribed, and in whom moral turpitude had nothing to do with the cause of their addiction; in dealing with these, good judgment should be used.

Drug Addiction and Crime.—James A. Hamilton, Commissioner of Correction, stated that men and women were committed to the workhouse in two ways under Sections 327 and 249a. Under Section 249a, known as self-committed, the persons applying either to the Department of Health or to one of the city magistrates might be committed and they were released only by direction of the medical authorities of the institution. Under Section 327 the person was committed by a judge, usually of the Special Sessions Court. When they appeared before him charged with some crime the judge, finding them to be drug addicts, committed them to the workhouse for treatment, which terminated by direction of the medical authority. They were then returned to court and were dealt with on the original charge as the court saw fit. A chart presented showed 240 men and 32 women received under Section 327, of which 114 men and 16 women had never been convicted of any crime to the best of their knowledge; 126 men and 16 women had served previous sentences. In other words, 52 per cent. of the men and 50 per cent. of the women had served previous sentences, some having been convicted two and three times. Of the 111 men and 5 women received under Section 249a, 59 men and 4 women had no previous record, while 52 men and 1 woman had served previous sentences. Finger print records on file in the speaker's office showed that over 50 per cent. of those addicted to the use of drugs had criminal histories. Some had had bad records prior to the use of drugs. Most had gone into criminal life as a result of the drugs, because those who had a craving for the drug were not sane or rational persons, and pleading with them to abandon the use of drugs was in vain. There were the rich "social" addicts and the poor, or "slum," addicts, the only difference between them being a matter of dollars and cents. Were the drug to be withheld from them you would find them pretty much alike. Evidence showed that the commercial physician had absolutely no intention of "reduction." A terrible result of ambulatory treatment of drug addiction was seen recently in the Tombs Prison. The victim was a young man who for seven years had been addicted to morphine, heroine, and cocaine. There was not a square inch on the thighs, abdomen, and arms that was not covered with an abscess or an angry looking ulceration. He had received 40 grains of heroine and 10 grains of cocaine every day from one of the commercial doctors. This case showed very clearly the danger of ambulatory treatment and the awful menace of the commercial doctor. Once drug addiction became firmly established a positive cure was difficult, and the only way it could be accomplished was through institutional care and treatment. It was rare to come in contact with young men between the ages of sixteen and twenty-one years who were confirmed alcoholics, while with narcotic drug addicts the genèral rule was that addiction was present mainly in youths from sixteen to twenty-one years of age. This was really the development age. Narcotics hindered development, and boys and girls were forever wrecked while still in the development period. Alcohol was slower in producing deterioration than narcotic drugs. The will power and moral fiber were not so rapidly affected by alcohol as by opium and its derivatives. As a consequence it was quite easy for a person who began to drink to stop abruptly without any bad effects. Even a whiskey drinker might take two or three glasses a

day for months and stop without any pronounced after-effects. On the other hand, if a person took opium or its derivatives for three months steadily, taking three hypodermics a day, he would become a true addict, and if he were to stop abruptly he would show decided withdrawal symptoms. As a rule, addicts must increase the dose as they went along in order to obtain the desired results. One of the greatest points of contrast between the two addicts, however, was in the method of administration. Alcohol stimulants were always taken through the mouth. Opium and its derivatives were usually taken by hypodermic or by sniffing. As a result of hypodermic administration one found abscess formation, ulceration, and disfigurement of the body, because the addict was not particular as to the sterilization of the needle or the point of injection. In "sniffers" of the drug nasal perforations occurred. From investigations and studies of the Department of Correction, it was believed that the Federal Drug Act should provide that all drugs coming into the United States, from whatever source, and all drugs manufactured in the United States, should be placed under the supervision of the United States Public Health Service. The United States Public Health Service should sell or dispense proper quantities of the narcotics to the State Health Department of each State. Legislation enacted by the State should provide that the State Health Department should sell or dispense narcotics deemed necessary to the Department of Health of each city or local community. The Department of Health of each city should open stations in the city at which place the physician, dentist, or veterinarian might obtain what he required, and to which place a drug addict might go and receive relief for his immediate condition; that was, not to receive a certain amount of the drug to take away with him but to receive a hypodermic injection at the station. After receiving temporary treatment, the addict should be given a card addressed to a certain hospital set aside for drug cases to which the addict must go to receive treatment. After being relieved of his craving for the drug, the addict should be sent to a farm or sanitarium, at which place he should remain for from three to six months for building-up treatment. At the end of three to six months, the addict should be released and placed on probation for two years or more, and required to report to the hospital where he was "taken off" the drug at least once every month, then and there to be detained under observation for twenty-four to forty-eight hours. If the addict showed he was again taking the drug he should be made to repeat the treatment. Lieutenant Sherb of the Narcotic Squad of the Police Department had recommended that each addict have a card with his picture and finger prints. It would, however, be advisable to provide for four such cards, one to be kept by the addict, one by the institution treating the addict, one by the Health Department, and one by the Police Department. All drug addicts should be sent to correctional institutions instead of to hospitals for treatment, as in a correctional institution they could not leave of their own free will. The supervision also was better and they could not come into such free contact with others. Again, in such an institution they could be finger-printed according to law. Conditions surrounding the addict were stricter and the physician had more direct control than was possible in any other hospital.

Dr. A. G. DUNNEZ of the United States Public Health Service stated that as a member of the committee appointed by the Secretary of the Treasury to investigate the situation in reference to the drug evil he had had the opportunity of making a general study of the situation throughout the country, and while he was not at liberty to give out the information obtained by the committee, he felt that he could make certain statements concerning his own investigations. At the present time there were no reliable records from which to form an accurate estimate of the number of addicts in the United States. It was found, however, that drug addiction was widespread; it existed in every part of the country. It was probable that many of the estimates as to the number of addicts were greatly exaggerated. Drug addiction appeared to be on the increase in congested centers. Twenty States, having probably a population of 10,000,000, had reported an increase in drug addiction. There was also considerable evidence to show that there was an increase in drug addiction in the prohibition territories. In prohibition districts paregoric and various patent medicines containing opium were being used in large quantities. Drug addicts could be divided into two classes, those belonging to the underworld and those in good social standing. Those addicts belonging to the underworld usually acquired the habit through association, while those in good social standing acquired the habit through the physician either directly or indirectly. Such being the case, he believed there were certain measures which the members of an organization like the New York County Medical Society should support. They should lend their support to some movement which had as its object the securing of proper records from which one could form an accurate estimate of the number of addicts in this country. They should support an educational campaign which had as its object the education of the medical profession as well as that of the laity. The speaker was of the opinion that the medical profession made addicts through carelessness. He believed the number of dishonest doctors was small, though undoubtedly there were some physicians who were not honest. The education of the physician should begin in the medical college. The courses in pharmacy and therapeutics did not lay enough stress on the dangers of drug addiction. It should be pointed out to the medical student that he should administer no opiates in cases of chronic bronchitis, habitual headaches, insomnia, etc. The public should be warned of the danger lurking in self-medication with any of these opiates. It should be brought to their notice that when they asked for cough medicine they should be very certain before purchasing that it contained no opiate. An organization of this kind should lend its support to research which had as its object the study of the mechanism by which drug addiction was acquired and of the phenomena of withdrawal looking to the discovery of some form of treatment that would be effective. The ambulatory treatment of drug addiction should be condemned, as it was doubtful if a man could be cured of drug addiction in that way any more effectually than he could be cured of alcoholism by such a method.

Dr. J. P. DAVIN spoke somewhat at length in opposition to the registration of drug addicts or to having their pictures taken. He felt that the Whitney bill was an exploitation of the medical profession and that public health officers were trespassing on the rights of the private practitioner.

Dr. E. S. BISHOP expressed the opinion that Judge Collins was the man who had spoken best this evening, because he knew just what he was talking about. There was no panacea for drug addiction and it could not be controlled by legislative administration. The cure of drug addiction depended upon the work of the individual doctor, on his experience, honesty, and intelligence. One per cent. of drug addicts might have been made by the medical profession; the rest were due to environment. This was true of the addicts that had come to the Health Department Clinic. Mr. Matthews stated that according to the ruling of the Supreme Court the physician could only treat the drug addicts with the object of curing him, but it should be remembered that they could not cure some addicts and they had to do something for them or the addicts would resort to the peddler for their supply. While he did not wish to be critical, he must take issue with the statement that all narcotic addicts were liars; all addicts were not liars. Any individual might become an addict to whom opiates were administered in sufficiently large quantities over a sufficiently long time, as a result of which some change had taken place in his body which made the opiate a necessity. The gradual reduction method did not cure drug addiction. Dr. Blair of Pennsylvania in a recent article stated that the gradual reduction method was the least preferable and he agreed with Dr. Blair. There was no method that had not had its successes and also its failures. As to registration, there was not the slightest objection provided people stopped talking about drug addiction as they did. If drug addicts were simply registered as people who had drug disease there could be no objection to it, but when they called all drug addicts liars and then asked the judge and the minister to come and register, that, the speaker said, was rather "rubbing it in."

THE NECESSITY FOR THE APPLICATION OF DIFFERENTIAL AIR-PRESSURE IN THORACIC OPERATIONS.*

By WILLY MEYER, M.D.,

For the second time the annual meeting brings together the members of the American Association for Thoracic Surgery.

This young organization, embracing members of the medical profession who are interested in the study of diseases of organs situated within the chest, saw the light of day at the time of the meeting of the American Medical Association in New York City, on June 9, 1917, and celebrated its first birthday in Chicago, on June 9, 1918.

It would be difficult to begin this second meeting better than by repeating the words with which the first, amidst a rising vote of thanks, was closed: "Our Association is proud and gratified to have it spread on its minutes that Dr. S. J. Meltzer, the renowned physiologist and internist, the man who has done so much for the evolution of thoracic surgery, was its first president."

If I might speak my inmost thoughts, I would say, I should have felt happy, had there been no successor, and had Dr. Meltzer adorned the presidential chair for another year, nay, for life. But he willed it otherwise; and so, gentlemen, by your kind choice, I stand before you as your presiding officer. Let me thank you most sincerely for the honor and your trust; they are highly appreciated.

The task of finding a topic for the time-honored presidential address has been made easy. Within the last year we have had new proof, that the usefulness of what I consider the *very foundation of modern thoracic surgery*, viz., the principle of employing "differential air-pressure" in the course of our operative work within the thorax, has not yet been generally recognized in its importance as a life-saver.

Hence, it appears to me appropriate that I should devote this address to a discussion of the place occupied in thoracic surgery by differential pressure apparatus, using the words in their widest sense, *i.e.* including all such apparatus and methods as we know of. In again calling attention to the necessity of their use in thoracic operations, I feel certain to be voicing not only my own personal opinion, but to be putting on record the sense of the majority of surgeons in this Association.

*Presidential address at the second annual meeting of the American Association for Thoracic Surgery, Atlantic City, June 9, 1919.

Let us see just what does occur when a healthy parietal pleura is perforated. Which are the symptoms and sequelæ of the acute pneumothorax? Which are the physical and pathological conditions surrounding it?

"Observing a deeply narcotized dog, whose pleura has been incised in experimental surgery, a very typical and characteristic clinical picture will be seen to develop. Immediately after the opening of the pleural cavity and the subsequent prompt retraction of the lung, a brief cessation of the respiration occurs by reflex. This is followed by sudden, almost projectile attempts at inspiration and expiration. The entire accessory muscular apparatus is called into strenuous action. The thorax moves up and down over the collapsed lung which is seen lying immovable in the depth; its originally glistening surface has assumed a congested appearance, and its normal pinkish color has given way to a dark grayish-red. Soon the frequency and the depth of the respiration increase, as may be observed by watching the excursions of the chest wall. At the same time the respiration becomes irregular. After a few minutes the symptoms are less stormy, the respiration becomes quieter and more regular, but slower and deeper than under normal conditions. This slowing up of the respiration, which gradually increases, is produced by the lengthening of the expiratory phase. A little later only brief inspirations occur at longer intervals. Soon the respiration and, therewith, the heart's action stop completely." (Sauerbruch).

Experiments further show that when both pleural cavities of the dog are simultaneously opened, respiration soon ceases, subsequent to most violent efforts of nature to hold back the waning life by means of very deep inspirations and expirations. Death occurs by suffocation.

In unilateral acute pneumothorax in the human subject, the disturbance is frequently less pronounced than in the dog, though it varies widely in severity in different individuals.

For the alteration in respiration various causes are responsible.

The principal rôle is played by the mediastinum. The anatomical organs and parts composing the mediastinum divide the thorax into two compartments, which latter are completely filled with lung. With the exception of the heart and large blood vessels the greater part of the mediastinal tissues represent a soft yielding mass, in which very little resistance to lateral pressure is offered.

Under physiological conditions the perfect equality of forces existing in the chest on both sides of the mediastinum keep the contents of the latter in

their normal position of rest. The part of the pleural sac that lines the mediastinal structures, chest wall, and diaphragm—mediastinal, costal, and diaphragmatic pleura—is in close approximation with the other portion of the pleural sac that lines the lung surface—the pulmonary pleura. The narrow space, separating the two pleural leaves, is filled with a viscid lubricating fluid which establishes cohesion between their serous surfaces, but leaves them free to glide over one another, like moist panes of glass which can be relatively shifted, but not forced apart, unless air is made to get in between them. Contact between the two surfaces is upheld by the air pressure within the lung which is always close to atmospheric pressure.*

Let us assume now that an incision of the chest wall has been made in the course of an operation, opening a "virgin" pleural cavity, viz., an intact cavity and without adhesions between lung surface and chest wall. At once air is admitted between the two pleural leaves, their cohesion is destroyed, and the air pressure on both sides of the visceral (pulmonary) pleura of the exposed lung is equalized. The elastic force of the lung tissue is thereby made active; the lung contracts to a mass of the size of a fist at its hylum—same as in the dog—and the opened side of the thorax is transformed into a cavity. Immediately the respiratory act becomes violently disordered. The excursions of the thorax leave the retracted lung unaffected, because there is no more contact between it and the chest wall; its lobes have lost their function. On the closed side of the thorax, on the contrary, the cohesion between parietal and visceral pleura, and therefore the function of the lung, has been maintained. However, under the difference of air-pressure on both sides of the mediastinum, when the thorax expands during inspiration, the mediastinal structures plus the collapsed lung and the heart with the large blood vessels, move forward and partly into the uninjured side of the thorax, the lung swinging like a pendulum suspended on the trachea as a rod. Inasmuch as the mediastinal contents are attached by means of the lower portion of the pericardium, also, to the diaphragm, the maximal lateral displacement occurs at about the center of the mediastinum. The whole mass moves in the same direction as the chest wall of the uninjured side, that means over towards the side of the lung which is still functioning, and interferes with its proper distention. The functioning lobes are thus, *during inspiration*, held near their normal expiratory distention, with a correspondingly reduced change of air in them and reduced oxygenation of the blood. In expiration the pendulum swings the other way; the whole mass flops back into the open cavity, the to-and-fro rocking of the heart subjecting the large blood vessels to severe bending strains in alternating directions. The mediastinum is now no longer, as under normal condition, the evenly balanced structure, upon which, and upon the rising diaphragm as a cushion, the collapsing chest walls squeeze the air out of the lung through the narrow glottis. With the mediastinum yielding to the one-sided pressure upon it, the air pressure within the lobes of the uninjured side only gradually rises high enough for escape of the tidal air by way of the glottis. A part of this tidal air rather finds an outlet into the incompressible portion of the bronchial tree of the lobes of the collapsed lung where it has but atmospheric pressure to overcome, and not the additional obstruction represented by the glottis. Thus the main bronchus of the collapsed lung with its first and second divisions—which, as just stated, have retained their normal size and shape on account of the cartilaginous rings within their walls, same as the trachea—becomes a "re-breathing bag" for the functioning part of the lung. In this way the collapsed lung appears to have an inspiration during the expiratory movement of the thorax, the air for it, however, not being furnished from without, but representing a part of the expiratory tidal air of the functioning lung; that means air which should have left the respiratory system by way of the glottis. The volume of the tidal air is thus still further reduced, with progressive vitiation of the shifted air.

At the same time a persistent chronic "hyperemia" invariably develops within the collapsed lung on the injured side. Its presence there was proved by most interesting experiments conducted by Cloëtta of Zurich, Switzerland. This phenomenon has so far, it seems, not received the attention which it deserves. The hyperemia of the collapsed lung on the injured side naturally reduces the quantity of blood in the general system, which, as stated before, is also altered in its quality by insufficient aëration.

The described interference with the normal exchange of gases in both sides of the lung causes a gradual accumulation of carbon dioxide in the system. This, in turn, produces a steadily increasing irritation of the centres of respiration and circulation by way of the pneumogastrics. In most instances this "vicious circle" soon becomes established after incision of the thorax. Respiration becomes slower and deeper, the number of heart-beats is reduced, while the systolic volume of blood is increased. Dyspnea in its most characteristic picture develops and persists.

Such, in the human being, is the general course of the dreaded "acute pneumothorax." As stated above, it occurs only in a certain percentage of the patients, coming to operation. But who is able to tell beforehand "which" patient will be subject to its deleterious, or even fatal, sequelæ?

The symptoms of acute pneumothorax cannot and do not develop, if we prevent the collapse of the lung, that is to say, if we keep the lung on the open side of the thorax in distention and thereby steady the mediastinum. This can be done by the em-

*The intrapulmonary pressure becomes slightly reduced (negative) during inspiration, because the distention of the thorax runs somewhat ahead of the air volume admitted through the glottis. On the other hand, the intrapulmonary pressure becomes slightly increased (positive) during expiration, because the size of the glottis does not allow the air to escape quick enough when the thorax contracts. A separation of the pleural surfaces under physiological conditions is unthinkable. It could occur only were the air pressure in the lung to drop below the value of the maximal elastic retractive force of the lung tissue, say 15 mm. Hg. This latter force differs at various points of the lung. It depends on the degree of excursion of chest wall and diaphragm with which the particular part of the lung is in contact. At the apex of the lung and along the spine the retractive force is considered to be practically zero; in front of the lower lobe it is ad maximum, varying at other points between these extremes.

ployment of apparatus embodying the "differential air-pressure" method.

Following upon scattered ingenious attempts at preventing the lung collapse with the help of apparatus, by French surgeons (Quénu, 1895, Tuffier, 1896), and American surgeons (Fell, 1888, Matas, 1898), it was Ferdinand Sauerbruch who, in 1904, by his experiments, his scientific investigations and his constructive genius, placed thoracic surgery on a safe basis. By the publication of his "Differential Pressure Method" and by his apparatus he gave to the surgical world the means for operating on *all* the organs situated within the thorax, under absence of disturbing physical conditions. He made it possible for the surgeon to operate within the thorax with the same tranquillity of mind and the same precision as in other cavities and parts of the body. The thoracic cavity thereby was opened safely to the surgeon, safely in the real sense of the word, viz., without forcing the operator into taking chances with his patient's life.

He also showed that, in case of injury to the intra-abdominal parenchymatous organs in the vault of the diaphragm (liver and spleen), work upon them could be safely done by the thoracic route (transthoracic laparotomy).

The differential pressure method aims at substituting the effect of apparatus for the normal forces sustaining the lung, which were cut out by the opening of the thorax. The apparatus has to supply a force which is equal to the elastic contraction of the lung tissue. The power used is air-pressure.

A difference in air pressure can be obtained:

1. By rarefying the air over the outer surface of the exposed part of the lung, that is to say, by producing there a pressure which is inferior to the atmospheric pressure within the bronchial tree and alveoli—negative (differential) pressure;

2. by increasing above atmospheric pressure the air-pressure within the entire lung—positive (differential) pressure.

Without exception all the various schemes devised for the neutralizing of the injurious effects of the acute pneumothorax are based on that alternative, first pronounced in so many words by Quénæ of Paris.

Making use of either one or the other of these methods in patients suffering from dyspnea in consequence of an acute pneumothorax, one will see the latter disappear and respiration become normal again. One will also see that the lung on the opened side normally participates in the act of respiration. It is further a fact that differential air-pressure interferes neither with the normal respiration nor with the normal circulation of the blood.*

The tangible, practicable result of Sauerbruch's labors was the negative chamber. Its construction and working, its advantages and defects are known to my hearers.

An amplified type of negative chamber, constructed on the basis of Sauerbruch's principles, I had built in New York in 1908, and I experimented with it until 1910. It was then remodeled and became part of the apparatus of the Thoracic Pavilion of the Lenox Hill Hospital of New York City. It permits of working under negative as well as under positive pressure in the course of one and the same operation. The change from one pressure to the other can be effected instantenously and without the necessity of reversing the position of the patient, assistants, instruments, etc., as would be required in Sauerbruch's chamber, were the pressure to be changed from negative to positive.

The rectangular negative chamber at the Lenox Hill Hospital is so far the only one produced in America. Originally built as a portable apparatus, and being a first attempt, it is naturally open to improvement in one or the other respect. A round design has on occasion been discussed, constructed so, that the chamber, like other operating rooms, can be washed out with a hose stream; also additions on basis of the Swedish chamber, in which the mask is used in combination with negative pressure, an improvement, which requires no modification of, but only a removable attachment to our present arrangements, and would insure undisturbed asepsis also in operations on the neck in the course of esophageal resections.

The negative chamber is an enlarged pleural cavity. It takes care with the same certainty and reliability of a bilateral as of an unilateral pneumothorax. It represents the most physiological apparatus in existence for complicated intrathoracic work on weak and reduced patients. It permits of the use of differential pressure under general or regional and local anesthesia. It is a splendid physical apparatus, which will always retain its scientific as well as its practical value.

But the negative chamber is expensive and stationary. Surgeon, assistants, nurses, and patient have to go to the apparatus; the apparatus cannot be brought to the patient. The same holds good for a number of positive (plus) pressure cabinets, in which the patient's head, that is to say, his bronchial tree, together with the anesthetist—entire or in part—are placed under increased pressure.

Sauerbruch's work made a great sensation in the surgical world and met with wide recognition. It also started many minds devising means by which the same ends might be obtained with less expense. In quick succession followed the mask method (Brat-Schmieden, Tiegel, Robinson (1908-1910), Meltzer-Auer's Intratracheal Insufflation (1910), and Connell's pharyngeal insufflation (1912), adapted to thoracic surgery by Branower (1913).

Tiegel worked out his apparatus on the basis of the experimental finding that lack of oxygen is the final cause of death in acute pneumothorax. He proved that 1 mm. pressure from a tank filled with pure oxygen suffices to avoid trouble. His splendid practical apparatus is extensively used in European clinics, and should, particularly for use in emergencies, form an integral part of the equipment of every operating room in our country, too. Tiegel's apparatus can be quickly wheeled to the patient's bedside, a feature of great value in case of trouble in the after treatment of thoracic operations.

Meltzer-Auer's intratracheal insufflation represents the simplest and most nearly perfect of all

*A slight increase in pressure has been found in the pulmonary artery with some stasis in the pulmonary vein, also some decrease in arterial blood pressure, when using positive pressure. However, the alterations are of no importance so long as the differential pressure is not pushed, and this is never indicated. One can, therefore, claim that new risks are not incurred by the patient who submits to the application of differential air pressure during operation.

positive differential pressure methods. Every one of you knows of its well-deserved triumphant march all over the world, within the last eight years. In two directions the method calls for attention and skill: first, that introduction of the tube into the patient's trachea requires profound general anesthesia; and, second, that a person is needed who has been trained to make the introduction of the tube into the trachea properly and gently, without doing harm to the patient.

Intrapharyngeal insufflation, which was originally introduced by Karl Connell of the Roosevelt Hospital, New York, as a method of anesthesia, and later on adapted to thoracic surgery by W. Branower of New York, with the help of an ingenious portable apparatus, promises to become of greatest value for thoracic operations. By insufflating pure air, or air mixed with oxygen, into the pharynx, a sort of air-storage is formed in that locality, in sufficient volume and under sufficient pressure to prevent the flopping of the mediastinum in unilateral pneumothorax and to maintain proper oxygenation of the blood.

In a rough way foot-bellows and a plain rubber tube, introduced into the pharynx through the nostrils, can substitute the apparatus in case of emergency.

Thus, we now have at our disposal four useful methods for maintaining differential air pressure, from which we can select according to inclination, opportunity, and the needs of the case in hand, four useful, practical differential pressure methods, which enable us to avoid the occurrence of acute pneumothorax. Many of us use such apparatus in our thoracic operations to good advantage and feel that we do not want to be without them.

On the other hand there are a number of colleagues of high standing who are unwilling to accept differential air pressure as an underlying principle in thoracic surgery, and claim that they are able to get along nicely without its use.

Opposition certainly is wholesome and to be welcomed. It is necessary for the progress of science. But it must be opposition in the right direction. Of course, we all have to individualize. Why should not a surgeon, if he considers it advisable in a given case, do a thoracic operation without employing differential pressure apparatus? I myself have done it in many cases. However, what I claim to be necessary, and always have had in my own cases, is some kind of differential pressure apparatus close at hand, ready for instant use, should the necessity for its use arise in the course of the operation and the patient's welfare demand it. To my mind the time has passed when any surgeon is justified in saying "differential pressure in thoracic surgery is superfluous." To my mind it is wrong to promulgate such views.

For the sake of the proper evolution of thoracic surgery it is equally wrong, I believe, to want to give to the surgery of the lung a special, an exceptional place in thoracic surgery, as some authors have lately been inclined to advocate. We should not separate the surgery of the lung from that of the esophagus or any other intrathoracic organ, but should consider the whole field within the thorax an entity and look at it from a broad and scientific standpoint. We should not separate thoracic surgery into different categories. We speak only of "abdominal surgery," and there is only one" thoracic surgery."

In this connection I must briefly refer to the teachings that have of late emanated from a number of great European surgeons, who worked at the front during the last four years and recently traveled through our country lecturing on their experiences. Under the correct impression that air pressure difference was necessary for safe operating within the thorax, and having no apparatus at hand, they at first abstained in the war hospitals from active interference in chest wounds. Conservatism was their watchword in these war injuries. But, compelled by many unsatisfactory results, they finally dared go ahead without using differential pressure, and saw excellent results in many instances. With the object in view of removing all kinds of foreign bodies in the lung or pleural sac, they made an intercostal incision, cleaned the pleura, pulled out the lobe of the lung in which often the *x-ray* had previously located the seat of the foreign body, incised the lung, extracted the missile, stitched up the pulmonary wound, dropped the organ back, and closed the chest wall air-tight by suture. Many of these patients recovered.

But is it correct, on the basis of such satisfactory experiences in war surgery in a traumatized and often inflamed and infiltrated lung, and inflamed or infiltrated mediastinal structures, to assert that the acute pneumothorax is something quite negligible, something not worth taking into consideration? Is it correct, on the basis of experiences gained under unusual conditions, to brush aside the well matured conviction of a century that the acute pneumothorax rather is a matter not to be trifled with, to ignore the decades of endeavor to find means of overcoming its recognized dangers, and to draw the conclusion that differential pressure is a ballast in thoracic surgery? I personally think that it would be an error to accept such a conclusion. To my mind the operator of to-day has in times of peace no right to jeopardize and take chances with the patient's life, when science offers him the means of avoiding them. Would the surgeon of to-day dare omit any of the details of aseptic surgery, because the ingenious Spencer Wells, before the antiseptic and aseptic area, successfully performed a number of ovariotomies by simply washing his hands carefully in plain water before the operation? If a modern surgeon were to do this and lose one of his patients he would be condemned, and justly so.

Let us try for a moment to analyze the experience our colleagues have had at the front. For the sake of science it appears necessary to do so, to try to explain the seeming discrepancy between their experience and that had by surgeons when operating on the thorax at our public hospitals in times of peace. How can we explain the absence of worrying symptoms in many of the thoracotomies, when even five to six hours after the wound had been inflicted, the chest was opened freely by incision without the use of differential pressure apparatus?

The fact has been established in the course of the war that over 50 per cent. of the men with chest wounds died on the battlefield. The surviving cases reached the ambulance or field hospital. In them

the heart—usually young, strong, and not diseased—had withstood the acute pneumothorax and hemothorax, and the lung of the unopened side also had adapted itself to the changed conditions. If operated upon by means of an exploratory incision and without pressure apparatus, often the at first serious and threatening symptoms improved. Why? Simply because, as we all know, the wide open pneumothorax, the *free* access and exit of air, is better borne than the pneumothorax coming from a small penetrating wound, through which air has entrance, but very frequently an obstructed exit. After free incision air alone replaces the blood and air that formerly filled the pleural cavity. The mediastinal tissues are apt to be infiltrated with blood, so that there is little flopping. Besides, the surgeon pulls the lung out of the thorax and treats it as the case may require. The pulling out of the lung into the wound opening ("Mueller's trick") steadies the mediastinum still further. The lung is then attended to, the pleura cleansed, and the thorax closed hermetically by sutures; a temporary artificial pneumothorax is left behind. The latter, as shown by Bastianelli's splendid investigations on the Italian front, favors the healing of the injured lung and its gradual expansion with advancing absorption of air.

The results obtained by our colleagues in military service by means of aggresive surgery in wounds of the lung have certainly been briliant and deserve the highest praise. But to draw any sweeping conclusions from their experience *with refcrence to the question of whether or not the employment of differential air pressure in thoracic surgery in general is a necessity* would, to my mind, be a serious mistake. How many of the wounded, who died after thoracic operations, might have recovered, could some differntial pressure method have been employed during the surgeon's work, can, of course, not be estimated.

The simplicity of the above described operative procedure in war injuries of the thorax may perhaps have impressed particularly those who never before had intentionally entered the thorax in civil practice, and who now under war conditions were, by sheer necessity, driven to thoracic operations. Under the stress and strain of their work and their often unexpected brilliant results of radical interference, it can be understood that many were carried away by their enthusiasm, that they generalized and gained the impression that employment of differential air pressure in thoracic surgery is superfluous. But they forgot that traumatic chest surgery is only *one small chapter* of thoracic surgery.

This, "whether or not" to use differential air pressure in thoracic operations is, is seems to me, the most vital question of the hour for the further safe and rapid evolution of thoracic surgery.

The idea that differential pressure apparatus are superfluous, at least in lung surgery, has naturally also got into the medical press, and thereby been widely disseminated. What wonder, that our colleagues are bewildered and do not know which opinion to accept. But a few weeks ago I met a colleague at the Academy of Medicine in New York, who works at a hospital with plenty of accidental chest injuries. We got into a discussion on thoracic surgery and differential air pressure. He said: "Doctor, nobody knows at the presnt moment where he stands. If you and your friends of the American Association for Thoracic Surgery want to do the profession a favor, throw some light on this vital question and state whether you think the hospitals ought to provide means for operating within the thorax or not."

Most earnestly would I invite the colleagues who believe that thoracic surgery *in general* can well get along without provision for the maintenance of the physiologic difference in air pressure existing in the chest, to come into the arena for an open discussion of this vital question which has been agitating many minds for the last twenty-five years, particularly for the last fifteen years, and submit their experiences and case histories. Let us discuss this vital question fully, but let us settle it, at least among ourselves.

On the basis of practical experiences in this one chapter of traumatic chest surgery, gathered during the war, modern thoracic surgery in general—I beg to emphasize this once more—cannot afford to throw overboard what it has slowly built up within the last fifteen years, modern thoracic surgery in general cannot afford to loosen the safe foundation on which it rests, namely, the recognition of the absolutely vital necessity of having ready for use a differential air pressure apparatus whenever a free pleural cavity is invaded, whenever a "virgin" non-adherent pleura has to be traversed in order to reach affected organs lying beyond it within the thoracic cavity.

In the early part of November of last year I had the privilege of discussing all these important questions with the five members of the commission that had come over from England, France, and Italy to attend the American Congress of Surgeons. All five came to the Thoracic Pavilion of the Lenox Hill Hospital. They examined the differential pressure apparatus there on hand: the negative chamber and the positive cabinet, Tiegel's mask apparatus, and the apparatus for insufflation. After a prolonged talk, three of the five took my point of view and conceded the necessity of doing thoracic operations with proper preparedness for differential pressure, negative or positive.

And let it be remembered that mask method and insufflation method, intratracheal as well as intrapharyngeal, all work on the principle of positive (plus) pressure within the bronchial tree, that is, on the principle of differential air pressure.

Gentlemen, I would ask you, not to consider the foregoing remarks a reflection upon what other colleagues have said and done, but to take them for an honest attempt, based on personal experience and conviction, to assist in finding the truth, and to help in accelerating the evolution of thoracic surgery for the benefit of suffering mankind.

After all, the safeguarding of the life of the patient entrusted to his care is the first duty of the surgeon.

700 Madison Avenue.

A Function of the Internal Secretion of the Thymus.—Muller found that exhausted muscles in experiment animals—frogs, rabbits, etc., were restored to vigor by thymus injections. As between the muscle and its supplying nerve it was evident that the stimulant effect was upon the latter. We already knew that in animals extirpation of the thymus causes myasthenia.—*Le Progrès Médical.*

THE OUTLOOK OF MEDICAL PRACTICE.*

BY S. SQUIRE SPRIGGE, M.D. CANTAB.
LONDON, ENGLAND,
EDITOR OF "THE LANCET."

DR. SPRIGGE began his address by expressing a hope that in the reconstruction of professional medicine, which would follow the introduction of the Ministry of Health, professional activities would not be marked by the plethora of Utopian schemes which embarrassed so much of the best endeavours during the war. He insisted on the necessity, under the new Act, of making full use of the opportunities offered for cooperation between medicine and the public, pointing out that the Act itself had come into being, not as the outcome of a national scare in respect of the state of public health, but as a response to the powerful stimulus of increased medical knowledge and general scientific progression. From this point he continued:

If fuller use is to be made of medical science, not only for the treatment or the prevention of disease, but also for the education of the public in the right ways of living, of working, and of playing, it is obvious that the medical profession as a whole requires reorganisation; but to listen to some of our leaders one would think that to carry out this reorganisation the Ministry of Health has been invented. It has not; but the reorganisation of the profession inevitably follows in certain directions, for otherwise we cannot perform without an uneconomical waste of time and work the fuller duties placed upon us. We led the way. The medical profession showed the need for the Ministry of Health by demonstrating that to sound medicine the people must look for national salvation; our own organisation is a sequel.

Let us remember also that the Ministry of Health has not come into being as a scare policy. It is the outcome of a wider recognition of things as they are and not as some very eloquent persons would have us believe, a panic-stricken crusade against overwhelming evils. We must all allow that there is plenty of room for reform in the public and domestic health of the country.

The present industrial conditions have an obviously evil influence on the normal expectation of life, as is shown by such figures as these taken from one of the Registrar-General's publications. Of those surviving 15 years of age, the average period of life among agricultural workers is 67, while among purely industrial workers it is just under 50. Again, recruiting statistics have shown that in several trades half of the workers, by the time they have reached 40 years of age, are unfit for military service. In many occupations over a third of those employed receive sick pay for some period in every year, and I have no doubt that if this vague statement, which is borne out by insurance statistics, were analysed closely by the companies they could show that the calls upon them in some directions were truly ominous. The deaths from tuberculosis in this country are about 70,000 each year. As a proportion of those deaths have certainly been brought about by war conditions, whether among the combatants or the non-combatants, it is a risky statement to say that more people die from tuberculosis than from war; but the statement is regularly made with the appalling experiences of the world-war before us, and made so seriously that it must have a foundation in fact, though the deduction may be challenged. There is a wide prevalence of venereal diseases, and the infantile mortality in some of our large cities is appalling. The figures here are not given, because they vary so widely and on such different grounds that the average percentages convey nothing that has a local application, while it may be a local remedy that is wanted in the medical view.

Ministry not Panic Legislation but Evolutionary Reform.—Now, no one wants to make light of circumstances like these, and if it were because of them, and because of them only, that a Ministry of Health was required, it would be clear that the Ministry was a piece of panic legislation. But as a rule sudden and belated determinations to deal with widespread evils do not present a promising outlook, so that it is a good omen that we are able to show that, while acknowledging that our social and medical plight calls urgently for reformation, the Ministry of Health has been the natural evolution of a great deal of admirable public health policy, statesmanship, accomplishment, and endeavour which have marked the social history of this country for two generations. It is a coördination of efforts which have borne admirable fruit in many directions, and to some extent it is because of the success of those efforts that the knitting together of their activities, and a removal of overlapping in these activities were necessitated. We in the medical profession have much to answer for in the muddle that exists, but it is our virtues and not our faults which have brought the position about. The era of sanitation, as we now understand it, and for all practical purposes the whole of our modern system of preventive medicine dates from 60 years ago, founded though our wisdom is on the wisdom of our ancestors and even of preceding civilisations. During these 60 years our professional knowledge has developed to such an extent that we have driven State organisations hither and thither in their attempt to carry out the medical ideal, or to avoid carrying it out, as the case may be.

Poor-law of 1834.—The sanitary conscience, however, awoke many years before preventive medicine was in a position to intervene usefully. Some 90 years ago the social and economic conditions in England, grievously affected by the Napoleonic wars, produced a feeling that the health of the people ought to be a national care. That feeling, as we know, took outward form at first in what we should to-day consider a highly unphilanthropic form, for such laws as were made were mainly intended to confine the ills of the poor, as far as they were the outcome of disease, to their places of origin; prevention was not mentioned, although there may have existed behind the rough machinery of segregation a consciousness that eradication of the ills rather than a lopping of their branches and a topping of their shoots ought to be effected. But at any rate the need for making the health of the people the care of the State had become obvious, but only those who could read with sympathetic

*An introductory address delivered at the opening of the medical session at St. George's Hospital, London, on Oct. 1, 1919.

heart the signs of the times grasped the significance of the conditions in which a large proportion of the population were struggling, and the legislature found the removal of those conditions to be beset with the difficulties everlastingly associated with the alteration of established customs or the restriction of vested interests. The science of medicine had not acquired a familiarity with the ætiology of disease that could enable its professors to preach the doctrine of prevention with sufficient authority either to arouse the public conscience or reinforce the voice of reform. And so in 1834 the Poor-Law Commissioners, perceiving that ill-health was a principal source of pauperism and that the removal of the causes of ill health ought to be a more economical proceeding than the treatment of its consequences, could none the less conceive no course open to them save remedial treatment, in an economical way, of those whose ills were already past remedy.

Medicine, Meddle, and Muddle.— Then medicine, leaping forward in bounds to accurate knowledge, became first an official and later an inspiriting counsel for further effort, and sections of the community became alive to the fact that by sanitation there could be removed barriers to their health and happiness which were remaining erect with no better apology than could be found in their antiquity. As each section was roused it made its claim for relief heard, with the result that the remedy best fitting the circumstances was applied. Schemes of reform initiated in this haphazard manner were entrusted for their carrying out to various departments of Government and various local authorities, with a consequent overlapping of jurisdictions, and waste of energy and money, while the resulting confusion was worse confounded by the creation of new Government bureaux and the rearrangement of local administrative machinery. It is the rapid increase of medical knowledge which, *au fond*, has been the reason for such comic facts as that before the invention of the Ministry of Health no less than 8 first-class Government bureaux had charge of medical affairs. Medicine demanded the innovation, various Governments, having no uniform plan, met this demand by putting the burden on the nearest available back. The outcome was to make the care of the health of the people, as conducted in this country, a magnificent and illogical muddle, in which fine ideas and accomplishments, many of which elicit the envy of modern civilisation, are blended with the opportunities for extravagance and dissipation of strength inevitably associated with the want of a central plan. All this has been for many years perfectly obvious to the medical profession, as well as to men and women whose public life has brought them into contact with the truths of our social existence. With those enlightened people, as with us, the feeling has been implicit that the health of the people, being a national asset, should have the national supervision of a State Department. And now the whole nation agrees.

The Future of the Medical Profession.— The medical year opens in circumstances so uncertain, so involved, and in many directions so difficult for the medical profession that those who are joining our ranks may be excused if they can know little of their worldly prospects. Perhaps this is for the best in their case, for the greatest driving force which the medical student can possibly possess is his desire to get into the service of healing, whatever the conditions may be. The best student is he whose first object is to gain admission to this service, influenced by the certainty that he may become a power for good and unfettered by the warnings of self-interest. But others besides the new students must be in some doubt where they stand, and I should like at once to state my absolute conviction that the conditions of medical service are not at the moment unpromising because they happen to be sharing in an all-pervading social muddle. On the contrary, while much that is dignified and some that is useful may certainly be jostled out of existence in the class and sectional fights ahead, it is perfectly certain that our science will receive new opportunities for expansion and, in my opinion, that our material prospects will improve. The whole of our advanced civilisation is in flux, and all the world rings with the cry of reconstruction. In every country leaders of men, made to admit by the revelations of the war the many weak joints in their social armour, have resolved that those joints shall be mended or that armour of a new pattern shall be employed. For the moment there is necessarily more confusion than reconstruction and, alas, more words than deeds. This cannot be helped. The necessary qualities in these days of transition are hope and belief—hope that the endurance which has carried us through days of trial will be with us in those of reaction, and belief that knowledge will triumph over ignorance when inequalities will be righted by a general sense of justice.

Opportunity for the Young Man.—He who joins our ranks to-day begins his medical life under the ægis of the Ministry of Health, a new Government department designed at one and the same time to provide for the people an efficient and orderly medical service and to secure for the members of that service better means of discharging their important functions. It is to my mind impossible that the activities of such a Government department, rendered necessary by the progress of medicine, should fail to operate in the near future to the advantage of medicine as well as of the community. There is at the present moment in the country a large number of young medical men at a loose end, and, qualified men though they be, they must be nearly as much at a loss to adumbrate their futures as any new student, but with the added perplexity that they may have wives and families to provide for. Many of them are full of new experiences and they are not finding opportunities for bringing those experiences to market in such a way that they can obtain good terms. The hardship felt by many of the medical men returning from war to practice is undoubted, but those who in this generation are suffering from the helplessness of medicine as an unorganised calling, should be ready for united action which will be of present worth, and whose benefit to future practitioners must be very great. Some genuine form of union is needed; some way by which we can find out what is the right medical view and what is the proper public claim, and can adjust these two things to the common satisfaction. For the Ministry of Health, designed for the public

weal, must be administered by us, and if we do it well we are worth our reward. A number of administrative or subadministrative posts, carrying regular salaries, and graded not only in accordance with the importance of the responsibilities incurred, but in accordance with the time to be taken up, will probably come into being soon; and it may be presumed that many of these posts will be part-time offices. Reorganisation of panel practice, which in some directions is imminent, will certainly place at the disposal of young medical men many chances of obtaining an assured livelihood and good scope for general or special clinical knowledge. When the panel practice, over and above the flat-rate payments of subscribers, brings with it a part-time appointment, the aggregate emolument will make the young medical man far better paid at the opening of his career than his father or his grandfather could ever have expected to be had he joined our profession. Hitherto one great and condemnatory criticism of the position has been that while the start is so good the future holds no greater promise. In panel practice a man may make almost at the outset what turns out to be his maximum income. It is clear to everyone that in the public employment of the future some flexible system of promotion will have to be laid down, so that the inexperienced man does not receive as much money as his senior. The income from panel subscribers can only go up if the practitioner increases the size of his panel, and while for physical reasons this may be an impossibility, for public as well as scientific reasons, it is an undesirable form of success. Justifiable comment on the position of panel practice has always been that the good start does not necessarily ensure the good fortune, and if we had come as a profession to any common conclusion we should realise that this is the main direction in which panel practice requires reform, once the question of proper emolument has been settled.

General Practice in the Melting Pot.—But the meaning of all this is that general practice in Great Britain, as we have hitherto understood it, is largely in the melting pot. In a few years' time there may no longer be a group of family practitioners having sole charge of the health of certain districts, each of them supposed to represent all the medical and surgical wisdom required in that district, save where the Ministry of Health as medical heir to the Local Government Board or the Board of Education, annexes a portion of the burden and therefore of the enumeration. But the cessation of the old-time methods of general practice will go hand-in-hand with added opportunity, both for specialisation and for the passage from the ranks of general practice to those of hospital surgeon and physician and scientific expert. For there will be no class of general practitioner separated off from hospital surgeons and physicians, from specialists, and from officials. The principal hospitals, becoming centres of scientific medicine in their localities, will be officered by men who, by fusion of duty with the general practitioners of the neighborhood, will make of the whole of the medical officers one general scheme for the good of the populace. The medical men of the district will have beds in their own hospitals, and will receive for their patients the consultative advice of their fellows and the assistance supplied by a laboratory of chemical research. And I look forward to the time when the general practitioner, reinforced in this manner by close communication with all branches of the medical profession, will take his part in the education of the student.

The Bright Prospect.—This is the common derivative from many schemes for reconstruction and reorganisation. Something of this sort is bound to happen. The new recruits of medicine will be placed in regard to these large changes in a more favourable position than the young practitioners immediately preceding them, whose professional prospects have been so involved with the struggles of war. It requires no great spirit of propheey to say that all things in the social world are working in favour of a properly treated and properly remunerated medical profession. The position of medicine has risen steadily in public esteem, the association of medicine with every form of domestic, national, and international politics alike has become very close, and the demand for medical counsel in every direction will grow keener. The profession must gain in strength under such public support, and it is impossible that the question of emolument can always be decided in the future against medical interests. These things being so, let us remember that while the medical life has many charms, the work to be done is anxious and exacting beyond the reach of adjectives, while the portals of entrance are strictly kept. For this reason, as well as for those connected with the suspension during the war of medical education, it will be a long time before there is an over-supply of medical men. At the present moment young men are sorely needed in civil and in official or service circles. The conditions of service in the Army and Navy, Indian Medical Services, and the Colonial Medical Service, have all been steadily improved, and in particular the Army and Navy offer really attractive terms. And just as these services cannot very well challenge each other in rates of pay, so their rates of pay must influence civilian rates and maintain a good standard all round. Thus young men who are choosing the medical profession as a career will find that they have chosen wisely, apart from the delight and utility of the life. They are entering a profession which tends to be well paid, and the advent of the Ministry of Health on the scene must turn all the circumstances to the favour of medicine in the end, even though we have a trying time of transition. It is, however, to be regretted deeply that during this time no form of political union among medical men is really effective to help the profession in arriving at proper terms.

VACCINE AS A PROPHYLACTIC AGAINST INFLUENZA, AND LOCAL REACTION AS A GUIDE TO IMMUNITY.

By HORACE GREELEY, M.D.
BROOKLYN, N. Y.

WHEN one attempts to analyze the literature of the use of vaccine as a preventative of epidemic influenza he is confronted with several difficulties. In the first place most of the vaccines employed contained several other organisms, such as pneu-

mococci, as, for instance, did that employed by the army authorities, influenza bacilli being present but in much the smaller quantity, so that in many instances it is a question more of the value of pneumococcus vaccine in the prevention of pneumonia than influenza bacillus vaccine in the prevention of influenza. Again where employment of vaccine has been reported it has been used on everyone available without considering whether they had just previously had an influenza bacillus infection (and could therefore be considered as already immunized) or not. Further, where it has been used on a group but few of which probably had been previously exposed, no portion of the group has been set aside as a control (not given the vaccine) in order to compare results. Finally, where only a portion of a not previously exposed group has been immunized there has been no subsequent certain exposure of the entire group as would be required to test the efficacy of the protection.

Owing to newspaper statements there was a great popular demand for vaccine protection against the epidemic in this city last fall in which most physicians acquiesced. So great was this that the drug trade completely sold out its entire stock of "influenza" vaccine (mostly "shotgun" mixtures) and the City Health Department's Laboratory reported that it dispensed free of charge over 150 litres of pure influenza bacillus vaccine during the height of the epidemic.

Having had several requests for the vaccine from physicians of Brooklyn, I made up a small quantity, comprising 17 "strains," or cultures of the influenza bacillus (Pfeiffer's) from as many different cases of the epidemic, and it is of the observed effect of this (of which a little over 8 litres was eventually made and distributed) that I write. The vaccine was grown on blood-agar, washed off in saline, heated for one hour at 60° C., standardized at 2,000 million bacilli in each cubic centimeter, and preserved with 0.5 per cent. phenol. The dosage recommended for adults was: First dose, ¼ c.c.; second dose, ½ c.c.; third dose, 1 c.c., with an interval between each of from 2 to 3 days.

Immunizations.—The most interesting experience in the use of the vaccine was with the charges of the Angel Guardian Home, Brooklyn. Influenza had invaded the institution two weeks before, and 12 of the children were sick at the time with influenzal pneumonia. Children who were not ill, to the number of 166, were given one injection of the vaccine (0.25 c.c., containing 500 million bacilli), by order of the attending physician, Dr. C. H. MacVean. In order to observe the effects of the vaccine, Dr. MacVean kindly got the sister-nurse who gave it to record results, and it is from her record that I quote.

The children were divided into those who, since the advent of the epidemic, had had "colds" (as such might have been immunized by an influenza bacillus catarrh) and those who had not.

Children to the number of 60 had not had "colds"; and of these 40 (67 per cent.) manifested a severe local reaction (swelling and erythema in a circle over two inches in diameter); 13 (22 per cent.) a moderate local reaction (circle 1 to 2 inches in diameter), 5 (8 per cent.) a slight local reaction (circle less than 1 inch in diameter), and 2 (3 per cent.) no local reaction whatever. Constitutional effects, fever and prostration, were reported to have confined 30 of the 40 showing severe local reactions to bed for several days. Children to the number of 106 had had recent "colds"; and of these 13 (12 per cent.) manifested a severe local reaction; 15 (14 per cent.) a moderate local reaction; 18 (17 per cent.) a slight local reaction, and 60 (57 per cent.) no local reaction whatever. None had noticeable constitutional reactions.

No case of influenza developed among the immunized children after their prophylactic immunization.

The Wharton Steel Co., of Wharton, N. J., had had a severe epidemic among its 800 employees which prostrated or frightened a large percentage thereof, so its officers resolved to offer prophylactic immunization to all of them. However, only about 200 took advantage of the offer, most only taking the first injection. As all of these employees may be considered to have been exposed to the infection, possibly even to have had it, before the vaccine was administered, they are mentioned only to state that not in more than one or two cases was there a reaction either local or constitutional following the injections. No cases of influenza were subsequently reported among those given the vaccine, although a considerable increase in the number of cases in the locality was noted shortly afterward.

It is very difficult to draw any conclusions from the use of the vaccine by physicians in general practice since it would be impossible to say whether the individuals injected had previously had the disease, in at least "cold" form, or subsequently developed it. One Brooklyn physician used the vaccine on himself for a cough that he feared was the beginning of an attack of influenza. That night the cough was better, but the next day, being again troublesome, he took a second injection which failed to give relief. I examined his throat secretions, and found influenza bacilli therein. Another physician, suffering from slight bronchitis, in whose throat I detected the same organisms in company with various others, said that he had, a week previously, taken three injections of vaccine. These two cases are given as illustrations of two classes of cases in which one who did not pause to think might say that the vaccine had failed to protect. After a little consideration one realizes that, with cases of the first category, the infection had begun before the vaccine was taken; and with the second, that while influenza bacilli were present in the throat, other organisms capable of causing bronchitis were there also, and greatly exceeded in numbers the influenza bacilli.

As further evidence bearing on the occurrence of local reactions after influenza bacillus vaccine, only in the non-immune, Dr. H. J. Goubeaud (Brooklyn) told me that he had injected a family (with my vaccine) of 6 adults and 1 child. Three of the adults—actors who had just returned from the "road" (traveling out West) and therefore who had not previously been exposed to the epidemic—developed marked local reactions, while the other three and the child—evidently previously immunized by an attack, as may be assumed to have occurred, to at least the extent of a "cold," from their ex-

posure to the epidemic then at its height in this city—showed no reaction whatever.

Local Reactions as a Guide to Immunity.—The following are the principles governing the occurrence of local reactions after the injection of vaccines:

1 (*a*) In accordance with the principles of infection and immunity the injection into the body of a suspension of bacteria *free from soluble enzymes or other substances capable of acting upon the tissues* (such a vaccine as "tuberculin-R," containing only ground and washed bacilli) will not cause a reaction *if the body has not, ready formed, enzymes or substances capable of acting upon the bacteria.* (*b*) If the body should have already developed such enzymes or substances, a noticeable reaction can occur only when the dose of bacteria is such that the decomposition thereof effected by the body fluids results in toxic products which the existing immunity can only partially neutralize.

2. As pathogenic organisms are grown in the laboratory on material similar in composition to that of the tissues, and as the microorganisms are washed off with water, *bacterial enzymes and products of their digestion of the media accompany the organisms into any vaccine made therefrom.* Furthermore, as vaccines are rarely heated above 60° C., as most bacterial enzymes are only destroyed at higher temperatures, and as many poisonous products of bacterial activity withstand even boiling, we understand *that vaccines must contain substances capable of causing the phenomenon of inflammation* (*local reaction*) when injected subcutaneously in all in whom specific neutralizing substances do not already exist.

General deductions from (1) and (2): The conditions of principle (1) never occur in the use of vaccines of pathogenic microorganisms as at present made (except with "tuberculin-R" when a reaction could be expected only in case the body possessed previously formed enzymes specific for the tubercle bacillus, *i.e.* in a tuberculous person). Principle (2), therefore, is that to which we should look for the explanation of local reactions, and for guidance in prophylactic vaccination. By this principle we would expect that a dose of vaccine would cause a distint reaction (just as does diphtheria toxin in the Schick test) in those without any immunity to the products present therein, while no reaction whatever would be elicited in those with full immunity. In persons with a lesser degree of immunity a reaction varying accordingly would be expected.

Applying these principles to the experiences with influenza vaccine, detailed in the foregoing, we see why the two groups of supposed immunes and nonimmunes responded as they did. Of the group of children recorded as not having had "colds" since the advent of the epidemic, (*A*) 67 per cent. showed a severe local reaction; these may be regarded as having had no immunity at all; (*B*) 22 per cent. showed a moderate local reaction; these may be regarded as having had a slight degree of immunity; (*C*) 8 per cent. developed a slight local reaction; which indicated a considerable degree of immunity; (*D*) 3 per cent. of the group, showing no reaction, may be regarded as all that were fully immune.

Of the group of children that had had recent "colds," (*A*) only 12 per cent. developed a severe local reaction—totally nonimmune; (*B*) 14 per cent. a moderate local reaction—slightly immune; (*C*) 17 per cent. a slight local reaction—moderately immune; (*D*) 57 per cent. no reaction whatever—entirely immune.

It should be realized tht the specificity of the responses elicited in the above is very great, especially when we consider that some of the children in the group which had not had recent "colds" could have had slight catarrhs which had either passed unnoticed or had been forgotten, and that some at least of the "colds" recorded might have been from other infections.

Of the 200 employees of the Wharton Steel Company, all of whom had been exposed to, and had even probably had an attack of influenza, not more than 1 per cent. developed local reactions, on either of the three ocasions upon which doses were given. The cases in the practice of the physician mentioned (Dr. Goubeaud) showed that adults not previously exposed develop severe reactions to the same sized dose as was given to all the employees of the Steel Company.

General Conclusions.—1. The effects of the administration of vaccine made of the influenza bacillus upon those who had previously presumably suffered from the epidemic of last year, and upon those who had so far escaped it, are exactly those to be expected under the principles of infection and immunity.

2. By observance of the local effects of a dose of vaccine one may determine whether the individual possesses any immunity against influenza, and approximately its degree.

3. A large group of nonimmune children, exposed to the infection in an institution where the epidemic had just started, were protected from an attack, and no further cases of the disease occurred in the institution.

4. As a direct consequence of the above, and, indirectly, through knowledge of the protective qualities of vaccines which give rise to similar phenomena when administered in the prophylaxis of other diseases, we may conclude that vaccine made of a mixture of different strains of the influenza bacillus has a definite protective value in preventing influenza in those not already immune to the disease.

BACTERIOLOGICAL NOTE.

As there has been some dispute as to the bacteriological cause of the epidemic, a few contending that a micrococcus was the etiological factor, and others that some unknown invisible agent, which could be made to pass through a filter, was responsible, a few words should be added in regard to the bacteriology.

Anyone who has grown cultures of the influenza bacillus is aware that some strains, at least, can be grown in serum-media in form indistinguishable from micrococci. Furthermore, that such forms, while they may be stained to show Gram-negative, are not necessarily so, as Gram-positive individuals and entire smears can be obtained.

From this and the well known fact that, in most cases of the epidemic, typical influenza bacilli could usually be obtained from the upper air passages, while coccoid forms were most frequent in the sputum and lungs (where the influence of blood serum and other conditions affecting growth can reasonably be assumed to be responsible for the morphology of the organism, since serum-media have this tendency) it seems probable

that the mass of the so-called cocci occurring in the sputum and lungs are coccoid influenza bacilli.

Influenza bacilli are classed among the smaller organisms, and as most pathogenic bacteria can be so grown and filtered as to permit considerable numbers to pass through any of the filters which have been used in attempts to prove that the virus of the epidemic was beyond the ken of the microscope, it is inconceivable that the filter-passing test should be considered a criterion of the usual size of the average organism of this or of any other infectious process.

The following quotation is given as commentary upon the failure of some investigators to find the influenza bacillus in cases of last year's epidemic.

"One of the puzzling features in connection with the bacteriological investigations of outbreaks of epidemic influenza has been the varying frequency with which Pfeiffer's bacillus has been detected in different communities. There has been a suspicion that variations in technique may have accounted in large part for the varying results, and that this is an important element is shown by the following circumstances:

"During March, 1919, an outbreak of influenza occurred in a western State. In this epidemic a very skillful bacteriologist failed to detect the influenza bacillus in appreciable numbers of cases, though he used approved methods which had given him positive results earlier in the pandemic.

"In order to determine how far the chosen method was responsible for the failure to detect the organism, the Public Health Service detailed two bacteriologists, who had been able to isolate the influenza bacillus from almost every case in an outbreak that occurred in an eastern community, to attempt the detection of the organism in the locality where others had failed. These workers succeeded in cultivating the organisms from about 80 per cent of the cases of influenza studied. The cultures were made in four different blood media from swabs rubbed over the nasopharynx, while cultures made from the sputum of the same cases at the same time by the bacteriologist in charge still failed to show the influenza bacillus in a large majority of the cases." (U. S. Public Health Reports—August 29, 1919.)

COMMON COLDS AND GRIPPE.

By L. Duncan Bulkley, A.M., M.D.,
New York.

In the interest of humanity and at the risk of being criticised, I cannot help writing again, as I wrote a while ago, in regard to the supreme value of the measures which I have repeatedly advocated in common colds and grippe, as I have had evidenced in hundreds of cases. I am especially impelled to do so by my own personal experience.

Yesterday I had about as severe a cold as possible, which had been coming on several days, and had been simply neglected, and I sneezed and coughed all day using any number of handkerchiefs. In the afternoon I took one or two doses of soda, half a teaspoonful, and in the evening took five more, at half hour intervals, in warm water. At midnight I took one of the grip powders I have so long prescribed, ten grains of phenacetin with twenty of soda, with hot water, and went to bed with two handkerchiefs under my pillow. I dropped to sleep very soon, and slept soundly until called at seven-thirty, when I took another of the phenacetin and soda powders and found the cold entirely gone; exactly the experience which I reported before and which I have had many times.

Last year from October to late spring I wrote for the phenacetin and soda powders, ten grains and twenty, almost every day, and sometimes at least four times in the day, for patients threatened with grippe, and although I questioned many, many patients at subsequent office visits I have yet to learn of any failure to arrest the trouble.

I realize that I am making bold and almost unbelievable statements, but I only ask that the profession make trial of what I have here written and report the results, good or bad.

To be successful the treatment must be carried out rigorously and fearlessly in the full and repeated doses mentioned, for many physicians to whom I have mentioned it have questioned the size of the dose, and feared to give it. I have never known an unpleasant effect, except in one lady whose lips turned blue, causing her to be anxious; but this soon passed off, and I learned afterward that she had always been peculiarly sensitive to the least administration of any of the coal tar products. I have frequently had patients who took a dozen powders within a day or two, with only good results.

In my own family I have in past years and recently treated some cases in which the grippe had already advanced considerably, with fever and great prostration, and will mention a single case occurring last winter. One of my servants, a strong, vigorous girl, of about 25 years, had been so sick for a day or so that the other girls had refused to attend her, fearing the grippe. I learned of it on Monday morning and at once gave her myself one of the powders with hot water, leaving others for her to take every two hours. When I first saw her she was in bed, very sick, with a medium high temperature, the head and neck bound up on acount of her sore throat, and complaining greatly of general aching pains. At five or six in the afternoon she was feeling much better. I gave her an active cathartic of blue mass, colocynth, and ipecac, and had the powders continued every two hours, if she was awake. She was also to drink as much hot water as convenient between the powders, but not to take a particle of food of any kind, which she had not done for twenty-four hours. The next morning at nine o'clock she was sitting up in bed, with the head and neck unbound, with no fever, and claiming to be well. I ordered her to take no food, not even milk, and ordered the powders still every two hours, until one o'clock, when she was to dress and go down to lunch. In the afternoon she was cleaning my office and remained well.

One cannot always explain why certain remedies act, nor can I tell how or why I struck on this treatment fully twenty years ago, which I have employed repeatedly with each recurrence of the grippe in these past years, certainly in hundreds of mild or beginning disease and also in more severe cases; in a former letter to the Medical Record I detailed some of them. Experience taught us the value of mercury, quinine, morphine, etc., without any true knowledge of their method of their action, and it must be acknowledged that there is much in the line of successful therapeutics which it is difficult always to explain logically.

If an explanation is wanted as to the action of the soda it is probably found in the rectification of the acidosis which presumably affords the proper soil for the infecting microorganism, while the repeated doses of the phenacetin probably are destructive to the same.

Medical and Surgical Lessons of the War.

COMMOTIONAL SHOCK CAUSED BY SHELL EXPLOSIONS.

FOCAL LESION PRODUCED BY CONCUSSION; THE COMMOTIONAL AND THE EMOTIONAL SYNDROMES.

BY DR. ANDRÉ LERI,
PARIS, FRANCE.
PROFESSEUR AGRÉGÉ A LA FACULTÉ DE MÉDECINE; PHYSICIAN TO THE HOSPITALS.

(*Concluded from page* 596.)

THE COMMOTIONAL AND THE EMOTIONAL SYNDROMES. Focal lesions following a shell explosion are rare, commotional troubles without signs of focal lesions are much less rare, and emotional troubles, with or without hysterical manifestation, are vastly more frequent. But, in the absence of blood staining of the cerebrospinal fluid or the ordinary signs of organic lesions of the spinal cord or brain, one is apt to mix or confound the commotional and emotional troubles, to make of both, according to the ideas of the moment, either organic or functional affections. The distinction is, however, not very difficult to make, if one will only study the facts, free from preconceived ideas, but attentively and as soon as possible after the accident.

In the first place one cannot, so to speak, have a commotional shock at will. A true commotion can be produced only under certain well-determined conditions, and the ignorance of these conditions has contributed not a little to the confusion of these accidents. We have endeavored to determine what are these conditions, basing the study upon our experience at the front.

The "commotional value" of a shell depends evidently upon its size, the power of the explosive, and the distance of the explosion; but we may say the nearness of the explosion is a much more important element than the mass of the explosive. There are extremely few commotions caused by shells of small caliber, although there are undoubtedly some, as in the case reported by Leclercq caused, at the beginning of the war, by a 77-mm. shell containing a very moderate charge of tolite, and also in the case coming under our own observation in which a commotion with focal lesions was due to the explosion of a hand grenade. But in those cases it is essential that the projectile should explode close to the subject—between his legs, so to say, or at most within two or three yards of him. Most of the true commotions have been caused by the explosion of a shell of medium or large caliber, but at the same time the shell must have exploded *very near*, eight or ten yards at the most for a large shell of 210 to 280 mm., charged with 16 or 17 kilograms of explosive. That is due to the fact that a shell explodes in the air, so to say, and that the really violent commotion-causing effects of the explosions are produced only in the immediate neighborhood of the cone of explosion, a cone which is less wide, with an equal quantity of explosive, in proportion as the explosion is more sudden, that is to say as the explosive is more powerful, more "breaking."

It is with persons as with objects: the destructive action takes place only in the immediate neighborhood of the explosion, the really dangerous zone is very circumscribed; beyond that there is a wave of atmospheric compression started by the explosion, a wave which travels with the speed of sound, about 340 meters a second, over a radius sometimes of several kilometers; the molecular concussion that it produces is sometimes sufficient to break anything as fragile as a pane of glass, but is insufficient to cause great damage either to buildings or to individuals.

Hudson Maxim recalls, a propos of this, the catastrophe occurring in the port of New York on July 30, 1916; an enormous quantity of munitions exploded, fragments falling into the neighboring waters, on wharves, ships, etc., in a rain of fire; there were, however, very few persons killed, and the material damage done to houses and other buildings in Jersey City, Manhattan, and Brooklyn was astonishingly slight, except for the broken glass. But the molecular commotion was propagated a long distance and there was an enormous loss in broken glass in the city of New York alone. A more recent explosion in Paris caused a degree of destruction exactly analogous to this. There was no occasion, therefore, for the astonishment that was expressed quite recently that an explosion of some hundreds of kilograms of powder did not produce a commotion in an officer who was 80 yards away when it occurred; it would have been surprising had the contrary happened, for a true commotion is not produced under those conditions, and it is because of ignorance of this fact that the term "commotion" has been so abused and that so many essentially dissimilar clinical pictures have been jumbled together.

Moreover, certain conditions, other than the mass of the explosive and the proximity of the explosion are necessary in order to cause true commotion; we must also take into account the *instantaneousness of the explosion*, to which the power of the explosive is proportioned; it is the detonator which in each primed shell (obus amorcé) determines this instantaneousness. The primed shell detonates (détone), that is to say the explosive burns with a rapidity of 3,000 to 10,000 meters a second; a shell which is not primed deflagrates (déflagre), that is to say the powder burns only at the rate of one-half to one meter a minute. A projectile which deflagrates becomes relatively inoffensive. This is one of the reasons why the explosions of munition depots, which have been rather frequent, have caused comparatively few cases of grave commotion, the shells there generally not being primed.*

On the other hand, the explosions of pieces of artillery are among the most potent causes of commotions, for the projectile which detonates within the cannon is already primed, the charge of the shell socket detonates at the same time, and the resistance of the walls of the gun is added to that of the walls of the shell.

Aside from the comparatively rare cases in which the explosion of the shell is purposely retarded by

*A detonation is a sort of explosive wave, propagating itself with great rapidity by a series of impacts and molecular concussions. A deflagration is a progressive burning, one portion after the other being invaded by the fire; this is what occurs when powder is ignited by a fuse. Detonation results from the ignition of the powder or other explosive by a detonator or primer, fulminate of mercury for example. The charge of a cannon explodes by deflagration; if it detonated it would burst the gun.

a special fuse, the shell explodes as soon as it strikes a solid body, and it explodes in the air. Thus the shells which fall on the roof of a shelter or on the parapet of a trench have little real commotional activity for the occupants of the dugout or of the trench. The shelter merely collapses under the weight of the shell or the edge of the trench gives way and stones are scattered about; the soldiers receive direct blows on the head from pieces of wood or iron or stones which cause phenomena of commotion; but there is no question here of indirect commotion from shell explosion produced through the intermediary of compressed air, but rather of a direct commotion with contusions determined by the impact of the solid bodies.

Even obstacles laterally placed break the force of the cone of explosion and hinder the production of commotions. We have thus seen a large shell explode at the opening of a shallow dugout, occupied by officers, and only those who were in the entrance were killed, the others escaping without injury except for contusions caused by falling beams. At the moment of the explosion of an immense munitions depot the entire wall of a wooden barracks was violently detached and thrown some distance away, but as if the force of the explosion had been arrested and exhausted by this obstacle none of the wounded who were in the barracks suffered from commotion.

FIG. 1.— Hemorrhage of the optic layer following commotional shock caused by a shell explosion. The patient was lying down when the shell exploded near him; he did not fall, nor did he receive a blow of any kind. Organic hemiplegia with heminanesthesia on the left side appeared within half an hour following the explosion, the anesthesia preceding the hemiplegia. There was blood in the cerebrospinal fluid.

What we have just said regarding the protective influence, much more protective than we would have imagined a priori, of the dugouts and the trenches, explains why a commotion from an exploding shell is hardly ever caused except in the open air, and why the ordinary shells projected by guns in a curving trajectory and exploding on the edge of the wall, but not in the bottom of a narrow trench seldom causes commotion in any of the men occupying the trench. It is especially for that reason that use has been made of aerial torpedoes which thrown up in the air at a short distance away fall by their own weight to the bottom of the trench and containing a considerable amount of explosive in proportion to the weight of the envelope may produce severe commotions; indeed, during the war of positions, in the course of which our observations were chiefly made, more than half of the true commotions were due to torpedoes.

We have dwelt with some insistence upon these questions of commotional etiology for the reason that they have received but little study hitherto and because the lack of knowledge of them has not been one of the least of the causes of the confusion of the clinical pictures, writers in general thinking that the enormous charges of explosives employed in modern warfare suffice to explain and justify the most severe commotions under the most diverse and we must say the most improbable conditions. But the "etiological conditions" which we have enumerated enable us to understand why, despite the employment of enormous charges of explosives, true commotional disturbances caused by shell explosions are relatively rare, infinitely more rare than the simple emotional troubles.

FIG. 2.— Syringobulbia in a case of commotional shock following a shell explosion. Note the inclination of the head forward, the enlargement of the neck, the sinking of the shoulders, the flattening of the face with effacement of the nasogenal fold, prognathism, and facial atony.

We are now in position to see how differently the commotional and the emotional disturbances comport themselves.

A. COMMOTIONAL AND EMOTIONAL SHOCK IMMEDIATELY AFTER THE ACCIDENT (ON THE BATTLE-FIELD AND AT THE FIRST-AID STATION).

Commotional Shock.—At the moment of receiving

a commotional shock the subject presents himself under slightly varied clinical aspects. We will merely mention two cases relatively rare. First, the foudroyant commotion: The soldier is near a large shell which explodes; he falls stricken and he may even die without a movement although he has not been touched by any fragment of the shell. In the second case, the patient suffers from commotion without loss of consciousness. There are indubitable examples of this character and we have referred to patients who had suffered from spinal or even cerebral hemorrhages after explosion but who had not lost consciousness. These cases seem to be rare. Between the two extremes we may say that the great mass of those suffering from true commotion lose consciousness immediately and more or less completely. The following are some types:

1. The soldier falls at the place he happens to be, for example, in the center of the barrage. He lies there without any regard for his safety, and he is taken up and carried to the first-aid station. He

Fig. 3. Same as shown in fig. 2, showing, in addition to the thickening and elongation of the neck, the right facial paresis (the mouth opening being an oblique oval), the deviation of the tongue, and the thinning of the lips.

is inert as a dead mass, the arms and legs hanging and swinging, the trunk sagging down, the head swinging, and the chin on the chest. On examination he is found to be unconscious, lying on his back, often bleeding from the nose or ears. If one lifts one of his limbs it falls back of its own weight. The patient does not move when he is pricked or pinched and he does not reply to any interrogation. The tendon reflexes are abolished or greatly diminished, *the pupils are widely dilated and but slightly responsive to light, the pulse is slow and feeble*, and respiration is prolonged and stertorous. The picture, indeed, is the classical one of complete coma analogous to the coma of a large cerebral hemorrhage. It denotes absolute physical and mental inertia, with inhibition of the motor and reflex functions of the spinal cord and also of the regulatory, sensory, and intellectual functions of the brain. The vegetative functions are also slow. This is the picture of complete and grave cerebrospinal commotional shock.

This condition lasts from several minutes to several hours, rarely twenty-four hours. It may terminate by death. The coma which is prolonged and complete becomes rapidly a fact of evil prognosis. The vital functions are extinguished in their turn progressively without any lightening. Nevertheless, however grave the symptoms may appear, the clinical picture in most cases grows less serious, ofter with remarkable rapidity, and at the end of a few

Fig. 4. Diffuse amyotrophy simulating a myopathy, which succeeded a diffuse paresis coming on during the three days following the near-by explosion of a shell. Note the lumbar lordosis and dorsal kyphosis, the prominence of the abdomen, the amyotrophy of the lower limbs with a tendency to genu recurvatum and of the upper extremities with dorsally flattened, hollowed, and half-closed hand, and the atonic aspect of the face.

hours the patient awakes, understands, and makes a few movements. He then from that time belongs to the other type of the commotioned which we shall now describe, and this modification has an excellent prognosis.

2. This subject of commotional shock also has fallen unconscious just where he happened to be, in the open, in great danger, alongside the exploded shell, but when he is lifted up, far from being an inert mass, like a rag, he shows a certain degree of rigidity, a certain physical tension. The limbs are not so flaccid and the head does not roll about. At the relief station he is seen lying down and appears just as inert as the blessé described above, but this is only in appearance for when one raises an arm or a leg the limb does not fall back so rapidly. If he

is pinched or pricked he complains and draws back his limb, and if he is questioned in a loud voice and in an imperative tone he replies, always slowly and painfully, in a monotonous tone, by monosyllables or stereotyped words, but nevertheless clearly, exactly, and without confusion. One patient replied by three words only to my question: "head," "shell," "cold," but these three words were not uttered just by chance, they were perfectly adapted to the question given. The patient does not even open his eyes during the examination and he falls back into a torpor immediately afterward as if his sole object was to make as little effort as possible. The tendon reflexes—patellar, Achilles, radial, olecranon, are all strong, full, and especially very quick, sometimes more or less unequal. The defense reflexes are also active and the leg is pulled back violently when one tickles the soles of the feet or when one manipulates the feet and the toes. We have not found the extension toe reflexes present in these cases. *The pupils are almost always dilated,* but regular and generally equal; they react feebly to light. The pulse is fairly strong, but it is slow, sixty, sometimes very slow, fifty, forty-five, or even less. The respirations are slow and rather superficial, especially the abdominal. In some there is no longer the picture of complete coma, at most it may be called subcoma. Inertia remains the dominant note but it is less complete. The inhibition is cerebral rather than spinal. The spinal automatism is relatively free from cortical control and this explains the exaggeration of the tendon reflexes and of the defense reactions. It is indeed the rule that in all cases in which the diffuse inhibition of the nervous system is incomplete the spinal activity is greater than the cerebral.

Fig. 5.—Same case as shown in fig. 4, the patient raising himself like a myopathic subject. Note the frog-like attitude, with sacrolumbar atony and marked curvature of the back, and the claw-shape of the atrophied hand.

This subcoma lasts for a short time, as a rule, and will have gradually disappeared at the end of a few hours, leaving only an intellectual obtundity and a physical depression analogous to what one observes in the type of commotion next to be described.

3. In this third type of commotioned shock the patient also falls and he remains a few moments on the spot, having absolutely lost his instinct of self preservation. He is raised up by stretcher bearers, but is able to support himself a little on his legs and is carried to the relief station by being supported under the arms. If they slacken a little on the way he tends to sink again. All movements may be very difficult as if painful and the foot seems to drag at each step as if attached to a ball and chain. He also, on reaching the first aid station, remains inert in the corner where he has been placed, but he lies on his side with legs drawn up and head firm. He moans without being touched and complains as soon as one moves him. He replies immediately to any question and replies also correctly. He complains of headache. He, however, does not know either where he is or why he is there nor what has happened to him, and as soon as the interrogation ceases he falls back into a state of inertia and obnubilative indifference to all that is going on around him. *Generally the pupils are dilated* and the pulse is slowed. Ordinarily he will come out quite rapidly from this stupor or torpor, but for some weeks he will still have a certain degree of physical and mental inertia and moving or thinking causes fatigue. He also has absolute amnesia of the accident itself and of the entire period of his torpor.

Often, however, these subjects are not even

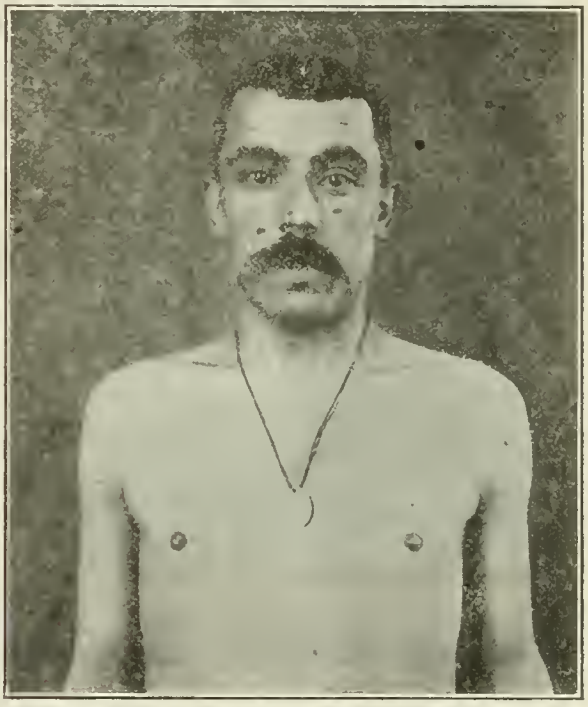

Fig. 6.—Same patient as shown in figs. 4 and 5. Note the facies which resembles in part that of a subject of myopathy—flat atrophic face, half-opened mouth, twisted lips, and also the squared shoulders.

evacuated to the ambulance in the rear, as they recover sufficiently to return to the front after remaining for some days in the little rest station for the slightly incapacitated (dépot d'éclopés) behind the lines.

These different conditions represent variable degrees of phyical and mental inertia and cerebral and spinal inhibition. They may be only successive stages of the same clinical picture. The mydriasis and bradycardia have seemed to us to be among the most common of the physical signs.

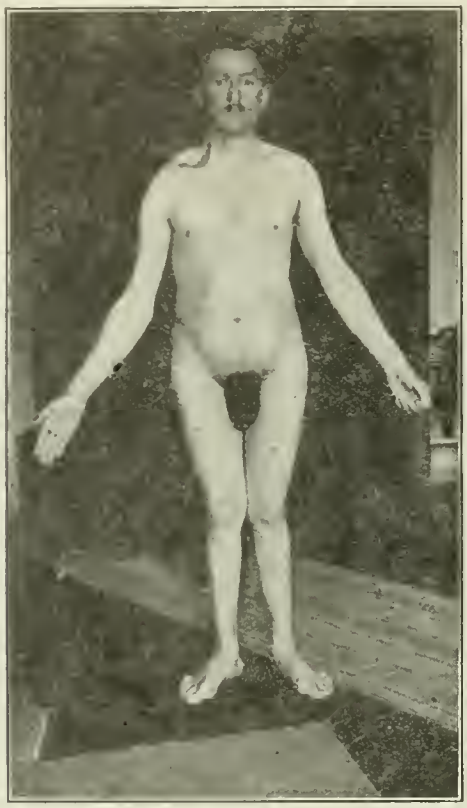

FIG. 7.—Irregularly disseminated amyotrophy appearing 15 days after the explosion of a 155 mm. shell. Note the pronounced amyotrophy affecting on the right the trapezius, the serratus magnus, the rhomboid, the deltoid, and the biceps; on the left the supra- and infra-spinatus, the deltoid, the biceps, and especially the muscles attached to the epicondylic ridges, the extension of the fingers, and the thenar eminences; and all the leg muscles on both sides. Note the sinking of the shoulder and the raising of the scapula with projection of its superior angle on the right side; atrophy of the forearm and closed hand on the left; and atrophy of the legs and claw-like contraction of the toes.

Emotional Shock.—The subject of an emotional shock is entirely different. Whether he is found in more or less immediate proximity to a large exploded shell, torpedo, or mine; whether he is simply found at some distance from a projectile of large or even of small calibre; whether he has witnessed even from a distance some terrifying scene in which an explosion has had no part; whether he has been thrown down or not—in none of these cases has he lost consciousness. He rises quickly if he has fallen down. He turns around if he has been going forward and, rapidly running if he can, or limping and staggering if he must, he reaches the first aid station without assistance. With staring eyes, pinched nose, pale face, and frightened aspect, he throws himself into the farthest corner of the post, on the ground or on a bench, and crouching down and curling up, he remains immovable.

If one examines him he does not lend himself readily to the process. He is trembling and rigid. The respiration is panting, the pulse is rapid and strong, and the pupils are rather small, but the tendon reflexes are neither exaggerated nor diminished. The pupils react well to light. The subject is not soiled with urine.

If he is interrogated he does not reply to the questions, and seems not to understand and to be mentally absent. This is the same man who, the next day in the ambulance, or later in the base hospital, will state, always without any bad faith, that he had lost consciousness and does not remember anything; but in reality he has not lost consciousness, and, as we have said, he remembers perfectly everything. In order to be convinced of this it will suffice to know how to question him. In the meanwhile he is only concerned with his own troubles, indifferent and inattentive to everything except to that which pertains to his self-preservation and the assurance of his own security. What proofs have we of this? These subjects are never found lying at the place where they fell, or unprotected in the midst of a barrage, and especially they never fly in the direction of the enemy. If they happen to meet on the way an officer who might arrest them they often do not wait for his orders, but threaten

FIG. 8.—Same patient as shown in fig 7, with the arms extended to the greatest possible extent. Note the incomplete extension of the right arm and the inclination of the trunk, the twisting of the right scapula, and the impossibility of extending the fingers of the left hand.

him. They do not put their threats into execution, however, for that would be to lose time, and they are altogether too frightened for that; and besides, they have not the least desire to injure any one, for their only idea is to flee. But this idea is absolute and imperative, however courageous they may have shown themselves previously. At the first-aid station they do not throw themselves down haphazard. They look at the roof and the walls, and sometimes rise abruptly to change place or to gain greater security.

If now we attempt to give these subjects who are apparently atonic and inert an injection of camphor oil, which is the regular practice for all the so-called "commotioned," it is not necessary to push down the piston of the syringe; it is enough simply to

insert the needle to wake them up and make them react, often very energetically. When the ambulance arrives to evacuate the wounded these men, who had appeared incapable of any voluntary act, rush out before there has been time to call them and jump into the wagon normally and with astonishing rapidity. If the ambulance cannot come quite up to the door, the corporal of the stretcher bearers has only to ask the surgeon which are the patients who ought to be transported on a litter, and all reply at once that they can go on foot. They can go much more quickly on their legs, and they can make much more of their sufferings than when lying on a stretcher.

It is the emotional type which we have just described, the pure emotional, so to speak. But even at the first-aid station there may be super added a series of manifestations belonging to hysterical phenomena—weeping, crying, convulsive seizures, spasmodic and tremulous choreiform movements, paralyses, contractures, stammering or mutism, etc. A remarkable fact is that these manifestations are in evidence only when the subject feels himself in comparative security, in trench, dugout, or in first-aid station especially. But the troubles cease as if by magic when the security diminishes, if the dugout is bombed or if the ambulance comes in sight of the enemy. Never, to my knowledge, has a convulsive, paralytic, or hysterical attack ever been seen when the subject was exposed on the battle front or in the midst of a barrage. It is by the addition of such hysterical crises that each emotional subject manifests, so to speak, his own reaction in his own fashion and according to his own fancy. Thus the varieties of the emotional seem to be much more numerous than those of the commotional. In reality the noisy phenomena are only variants, usually comparatively tardy, and in every case almost never immediate, since they demand comparative security for their production. The clinical picture of the emotional subject freed from these additions of a sometimes disproportionate exuberance is really an entity, as is that of the commotional. It is because one has failed to recognize this very simple clinical picture that one has too frequently confounded the facts, which are entirely dissimilar in their symptomatic expression as well as in their immediate prognosis, their late consequences, and their indications for treatment.

To sum up, on the field of battle that which dominates the subject of cerebral *commotional shock* is physical and mental inertia, more or less absolute at first, and then lightening from complete coma to simple obnubilation and atony; mydriasis and bradycardia are the usual physical signs. The subject of *emotional shock* does not really lose consciousness, memory, or the instinct of self-preservation, and he is not inert or agitated, physically or mentally, until the point is reached when he no longer feels that he is in danger; the most varied hysterical manifestations are a frequent but never an indispensable accompaniment of the emotional troubles, and then only when the patient finds himself relatively secure. The emotional subject is by far the most common in the first-aid stations. One will find hardly four or five true commotional cases to a hundred emotional.

SUBJECTS OF RECENT COMMOTIONAL AND EMOTIONAL SHOCK (IN THE FIRST-LINE HOSPITAL).

In the first-line ambulance the syndromes become often less distinct. The commotional subject who comes to himself and regains consciousness cannot help being more or less emotional retrospectively. The emotional subject who finds himself for the future in security has no longer all his physical and mental activity excited by the instinct of self-preservation, and is often only a very tired man, and as such, with depression and inhibition, he resembles the commotional. The mixture of morbid types is evident, but each of them keeps more or less the reflection of the differential characteristics which we have described as present at the moment of the accident, and which correspond up to a certain point to the anatomical lesions.

Commotional Shock.—The commotional subjects who have been brought to the hospital some hours, or even days, after the accident, are still essentially characterized by their inertia, with its two principal traits, *physical asthenia* and *mental obnubilation*. Often brought on stretchers, they rise if they are told to do so, enter into the ward or mount the stairway, assisted under the arms, slowly and mechanically, like automatons, as if they were mentally absent, and when put to bed they lie stretched out on the back, or sometimes on the side with legs drawn up. They move little, and their movements are slow and difficult, often like those of ataxia or dysmetria. They remain in the position in which they are placed, and even cataleptoid attacks are not so very rare. Their eyes are sometimes open, though the lids are heavy, and the patients never express surprise, never know where they are, or how long they have been there, or whence they came, and *they do not appear to care in the least.* However, they know perfectly well their name, age, regiment, their native place, and their profession. They have preserved all ideas the recall of which is, so to speak, automatic, and requires almost no effort. When they speak they give all this information very exactly, without any confusion, incoordination, or disordered ideas. More than that, they know sometimes the year and the current month, or even the day, and so far as one can judge they are not at all disoriented. But to every question they reply slowly and with difficulty, as if they needed considerable time to understand the question and to collect their ideas. They reply in a low and monotonous tone of voice, in chopped-off words, by monosyllable, as if they feared to make any superfluous effort. No amount of pulling about will disturb them and nothing is able to arouse them from their stupor. Left to themselves, they are always somnolent.

The tendon reflexes are generally amplified and especially lively, but without foot or patellar clonus, and there is no toe extension reflex. The pupils are most frequently contracted, and react feebly to light, and when they do contract to light there usually follows a secondary dilatation or nystagmus of the iris, denoting an instability of the iris. The pulse is ordinarily slow—60, 50, or below—but as it is essentially unstable we can formulate no absolute rule regarding it. In all cases the pulse is weak, the cardiac beats are feeble, and the maximum arterial tension is distinctly below normal. The mydri-

asis and bradycardia are among the most usual physical signs of the commotional syndrome.

Very often the subject is more or less deaf on one side or both sides in consequence of labyrinthine concussion, with or without rupture of the drum and hemorrhage of the ear. This deafness may lead us to regard his obnubilation as deeper than it is in reality. Ordinarily the resistance to the galvanic current is notably increased when one tests the voltair vertigo, and on lumbar puncture one often finds the cerebrospinal fluid hypertense. These troubles would have a diagnostic value if they were not observed also as sequelæ of marked vasomotor and secretory troubles caused by strong emotions. In proportion as the subject comes out from his inertia we note two symptoms which are rarely absent, namely, headache and dizziness, which are common symptoms following any cerebral lesion, traumatic or not. It is also as the patient comes out from his inertia that one can best study his intellectual condition. We find then that the intellectual activity is slowed and diffusive. The reason, the will, and the affectivity are blunted, but not extinguished, and the first smile of the soldier is often for the wife or mother who comes to his bed. He also recalls the physician or comrade who has been in his presence and the name of his native village. The memory is not very profoundly affected. We have said that the subject recalls elementary ideas which concern his name, age, country, regiment, etc., and, more than this, he often knows his address in the city or the department in which his village is situated. It is even not very uncommon that while apparently inert he replies quite exactly to any reiterated demand of mental addition or multiplication, but in a tired, dull, monotonous voice, as if to get rid of somebody who is bothering him. It is true that the replies are not always obtained easily, for these patients are depressed, inhibited, obtuse, so to speak, and they often resemble strongly the subjects of confusional insanity; but they are neither confused nor disoriented, nor is there any mental incoordination, nor absolute or irregularly dissociated amnesia; they simply do not make any effort, which is one of the essential elements of true confusion. A serious examination will prevent any confounding of the two conditions, and from what we have seen we can say that true commotional subjects are not, as a general rule, true confusional ones in the psychiatric sense of the word. At least we should not give it this term in the popular sense, which is so vague, or regard it as a synonym of mental asthenia.

The memory, however, fails utterly in one direction in the case of the commotional subject; he has *no recollection of the accident itself* and of a longer or shorter period of time following it. Very often, when the shell which exploded near him was the only one there at the time, he heard it coming, and sometimes, though less frequently, he remembers seeing the explosion. But at this exact minute his memory deserted him, and he recollects nothing that followed. Occasionally he does not remember hearing the shell. But whether or not he remembers hearing or—rarely—seeing the shell, he cannot say whether he was knocked down by the explosion, thrown into the air, or covered with earth, or how long after the accident he was picked up or by whom he was picked up; nor can he recall whether it was day or night when he was moved, by what means he was taken away, or to what hospital line he was evacuated. Sometimes the patient came to in the first-aid station, sometimes not until he gets to the hospital, or even several days later. As to what has happened in the meantime his mind is a perfect blank.

As to the lapse of memory, we can make a distinction between two periods. There is at first a period of complete loss of consciousness, during which the subject is wholly "absent" as regards the external world, neither seeing nor hearing anything, and so evidently being able to retain nothing in his memory. But soon he comes to himself, though not altogether; he sees and he hears, and if he does not have any mollution of this second period we may regard it as a case of lacunar amnesia. The following is an instance of this: D—— enters the ambulance, he replies to some questions, gives information regarding his name, his military position, and the place from which he came; he goes up the stairs and gets into the bed, which is pointed out to him, but on the morrow and the days following he has no recollection of all this. And, more than that, on the morrow and the following days one may have a talk with him during which he replies logically and very clearly, and may even give a quite straightforward account of something, but retains no recollection of what he said the morning before, nor even of what he has done up to the very moment of this conversation; there is evidently lacunar amnesia, and even fixation amnesia as well. But in a general way, and contrary to the prevailing opinion, if we put aside the lacunar pseudo-amnesia of the period of subcana or profound obnubilation, true lacunar amnesia and the continuous amnesia of fixation have seemed to us to be rare in commotional cases. The amnesia, at all events, begins with the traumatism; it is more or less anterograde, very seldom retrograde, very exceptionally bearing upon ideas acquired prior to the accident. However, it is well to make certain distinctions.

x The commotional subject is mentally beclouded, as we have said, and it is not a cause for surprise that he should lose, at least for a time, his memory of abstract ideas which he had previously acquired. The recall of such ideas in one who has not based on them his professional life (philosophers, mathematicians, professors, etc.) is by no means automatic, and it necessitates always a certain effort not only of pure memory but often of reasoning. One need not be a commotional subject; it suffices in ordinary life to be simply fatigued to know the effort needed to recall more or less abstract ideas. Now the commotional subject, mentally dull and inert, is incapable of making this effort. He will often appear to be amnesic or not according to the manner in which examination is conducted; it will be necessary to push him, to do the work for him, to put very general questions at first, making them gradually more and more precise, and interrupting the interrogation when the patient becomes too fatigued, and then one will often note with surprise the unsuspected number of facts that the subject can recall.

There is still another series of remembrances of the former life which seem to disappear with spe-

cial frequency; these are the remembrances of dates, of proper names, and of places; the commotional subjects seem particularly to have lost remembrances of the locations of their cantonments, the length of time they were kept there, the names of their officers, or even of their comrades. Now one must never have seen at close range troops on a campaign under the conditions of actual warfare to be astonished at this—the intellectual, emotional, and even affective indifference acquired by the great mass of soldiers in the course of three long months of primitive, almost animal and troglodytic life, exposed every minute to the greatest danger, is unimaginable Extraordinary as it may seem, if they do not remember the names of their chiefs it is often because they have never known them or else have never paid any attention to them. Their occupation is one of the barracks and not of the field of battle. As to the names of their comrades, they often do not know them either; they have not many comrades to whom they are attached, curiously or uncuriously, for they are too liable to lose them at any instant; affection is not in fashion under these circumstances, and those who help each other do so anonymously.

If one takes account of what has been said, and questions these men as soldiers at the front should be questioned, one will note that the subjects of a true commotion have almost never really lost the remembrance of the facts which preceded, even immediately, the accident. But as we have said, given their extreme mental and physical fatigue, we must make our questions gradually more and more precise; we should not ask them for a complicated recital the sequence of which would probably leave much to be desired; we should lead them on little by little, as if by the hand, from their last perfectly clear remembrance, that of their last rest cantonment, for example, up to the very place and the very moment of the explosion; and in order to arrive there it is of prime importance that the medical man himself should know the locality, the sector, of which there is question. It is not in the interior, after a more or less long lapse of time, that such a word can be carried out a slow work, and one as hard, perhaps, for the physician as for the patient, but an exceedingly productive one. It should be noted that the facts thus recalled and coordinated with the collaboration of the physician will thenceforth remain in the memory of the patient; but the same remembrances, left to themselves in the more or less lasting mental inertia of the subject of the commotion, will gradually wear themselves out, will be effaced as in every remembrance which is not sufficiently vivid or often enough repeated, and then when he arrives at the interior the man will be regarded as a subject of retro-anterograde amnesia.

We may, therefore, regard retro-anterograde amnesia as very rare in the subjects of commotion, and in this we shall find ourselves diametrically in opposition to most writers on the subject if we venture to make the statement applicable to all cases of cerebral traumatism; but we believe, on the contrary, that retro-anterograde amnesia is relatively a rather frequent symptom of certain localized lesions of the brain, and especially of contusion, the effects of which are so often superseded by those of commotion.

Emotional Shock.—The subject of an emotional shock at his arrival at the ambulance is generally not an inert mass like the subject of commotional shock but is rather bewildered, confused, and almost always a fatigued man. Often at first sight he seems to be as depressed as the subject of true commotion. He is somnolent, and it is necessary to lead him to his bed and put him in it. If he is asked a question he does not reply, but one must not be deceived by this, it is only pseudo-inertia and pseudo-obnubilation. If one disturbs him somnolence by talking to him or speaking loud in his ear he groans and trembles, and then looks at the questioner with frightened air, eyes wide open and staring, as if a prey to extreme anxiety or alarmed by a horrible sight. Furthermore, notwithstanding his somnolent air, he does not sleep, and in the course of his nocturnal insomnia he is delirious, often noisily so, and his nightmares are occupied by the vision which is always the same with perhaps some slight variations, namely, that of the accident which caused his trouble. The condition is furthermore exactly the same whether an explosion took place near or at a certain distance from him, or whether it was a case of assault or bombardment, or even a scene of carnage without explosions at all, and one in which the soldier has taken part only as a simple spectator without there being any possibility of his receiving a commotional shock. What dominates him always in his physical aspect as in the mental condition and in the preoccupations of waking or sleeping is anxiety occasioned by the accident causing the emotion. Except for what concerns the accident itself, whatever may be the question which one puts to these subjects, the reply is almost always, "I do not know." They know neither the day nor the place where the emotional shock was produced, nor what has happened since, nor what took place before the accident; if they are to be believed, they have lost memory completely. Almost all declare that they have had a "commotion," that a shell has fallen, or that there has been an explosion. There is indeed one memory that always comes to the surface, namely, that of the accident itself. It is not difficult to learn by some skilful phrases what is the remembrance that haunts them day and night. If one leads up the conversation to this subject the patient is often thrown off the track, and he starts, as if he had thrown off the gear, and the recital that he makes is animated and full of imagery to a point that one would not have thought him capable of, judging from his atonic and somnolent appearance some seconds before. Starting from the accident causing the emotional shock—the only clear thought, the only distinct preoccupation which monopolizes the minds of these soldiers—one can generally induce them to state the exact moment and place. The reply does not always come immediately. They do not always know what was the date or what was the name of the nearest village, but if one has patience to insist, one will see they know whether it was day or night, even whether it was at the fall of evening or at early dawn, whether they occupied a front line trench or one further back, and what was the name of this trench (the

trenches often have names marked on them like the streets of the city). In fact, one will find out that they are not disoriented as regards either time or place. Pushing the questions further, instead of being satisfied with the ordinary reply that they have lost recollection, if one asks where they were when they came to themselves the reply will almost always be that it was at the first aid station, or sometimes only on arrival at the ambulance. But how did they get to the first aid station? Because they had seen it in passing up to the front line, so that they knew where it was and they had gone to it directly; or, if they were out in the open, by first creeping back into the trench. By a progressive and adroit interrogation one also learns that if they were sometimes upset and momentarily bewildered by the shock, almost always *they had at no time lost consciousness,* and that it was not without a process of reasoning that they had escaped; and this is evident, however little the physician is acquainted with the place or with the indicated trenches and dugouts connected with them, etc. If he has the patience to take, as it were, the soldier by the hand and to conduct him in thought from the place of the explosion to the first aid station and from that to the ambulance, almost always he will find that the patient has preserved complete or nearly complete recollection of what happened after the accident. As to the remembrance of facts prior to that time, which is almost always more or less faulty, one can recall it in some way, generally more easily by starting from the accident, the center of the patient's memory, so to speak, and going back to the time when he entered the first line or back to the rest period, etc. Soon one will find in this way that the patient who seemed not to have retained any recollection of the period prior to the accident and to have lost sometimes all recollection for a greater or smaller number of days preceding, in reality has not lost any; *this subject of profound amnesia has no amnesia at all.* It is certain that memories recalled were never memories lost. They existed, but they had been covered over. If they had seemed to be effaced it was because they were dominated by another recollection, very absorbing and preoccupying, and very vivid also, the remembrance of the accident itself and of the emotional shock which was its immediate consequence. Concentrated in their emotion, presenting all the moral disturbances of the exhausted, and often all the physical signs of anguish, these subjects had paid attention to none of their surroundings. Everything was indifferent to them which was not their emotion itself or its cause. *It is essentially the attention which is lacking in subjects of a great emotional shock.* The entire field of attention is occupied by the obsessing memories of the accident itself. It is lack of attention which provokes not only the pseudo-amnesia but the pseudo-obnubilation and the pseudo-disorientation.

Thus we see that, while in the subject of commotional shock, and especially of cerebral contusion, the memory of the accident itself and of a longer or shorter period following, much more rarely of a period preceding, fails absolutely, in the subject of emotional shock it is this very memory of the accident which dominates him and monopolizes all his attention. In consequence of this lack of attention in regard to everything which is not the emotional shock itself, all the recollection of the period following the accident, and less commonly of the period preceding, may be covered over, but it still exists and may be recalled by suitable questioning. It is only later that these memories already hidden gradually become obliterated.

The inertia which marks the subjects of commotional shock does not exist to the same degree in those of emotional shock in either the mental or the physical field. Motility and sensibility are retained. The reflexes are usually normal. The pupils are usually contracted rather than dilated. The pulse is unstable, but more frequently rapid than slow, and the subject has the appearance of a tired man. He is often pale, without appetite, rapidly losing flesh, is somnolent during the day and unable to sleep at night. He often has marked trembling, has headache, fears and shuns noises, weeps spasmodically at the recollection of the emotional shock itself, and perhaps also of the danger which he has run; and finally he often has some hysterical manifestations superadded.

C. LATER PERIODS AND SEQUELÆ OF COMMOTIONAL AND EMOTIONAL SHOCK (AT THE BASE HOSPITAL).

Commotional Shock.—The subject of commotional shock may come out gradually from his torpor and inertia and regain after some days or weeks a nearly normal activity and mentality, retaining only slight fatigue and a "furrow" in his memory. This is the most frequent mode of evolution toward recovery. At other times, slowly and gradually, or after a temporary improvement which almost seems to be a cure, the progress begins to drag and the condition becomes, so to speak, chronic.

We have then the picture of prolonged cerebrospinal commotion. The characteristics of this prolonged form of commotion are again and always inertia, shock, and physical inhibition. On the mental side commotional shock is an inhibition of all the intellectual faculties. The patient replies slowly to questions, partly because he understands them with difficulty, partly because the ideation necessary for reply is slowed. The conversation is monosyllabic or in chopped-off phrases and ceases as soon as the question fails to support it; it must be sustained by force, so to speak, for it seems to be painful to the patient and if it is kept up for long it quickly becomes impossible. Writing is still more difficult than speaking, for it calls for more sustained effort, almost as much physical as mental. If one tells the patient to write down what he complains of, he will hesitate a long time before taking the pen, and with the pen in hand will hesitate again, and then will write a few words, or often will put it down without having written anything. All these movements are made slowly with a weary air and as it were mechanically.

Attention is very difficult to fix and every effort at attention soon causes extreme fatigue. This difficulty of attention has much to do with the slowness and almost impossibility of spoken or written communication. It is a prominent factor also in the disturbances of memory. It is because they do not pay any attention to it that the subjects of commotional shock perceive such a small number of things which go on around them and consequently

preserve the memory of but few of them. It is also because they do not pay attention that they register such a small number of facts which, however, they see and hear. It is because they do not pay attention that they acquire almost no new ideas, but the memory is lacking little or not at all. What the patient has not only seen but has observed is preserved and may be recalled by precise inquiry. The memory of events which have taken place long after the traumatism may thus be recalled, except that of the commotion itself and the following period of coma or subcoma. When one questions these patients with care one sees that they almost never suffer from fixation amnesia nor from retrograde amnesia.

The subject of commotional shock is not disoriented in either time or place. His condition is described as inertia and impossibility of thinking and still more of acting, and although his affectivity is also much diminished, he suffers in a more or less conscious way. Often he has the impression of the incurability of his condition and of the impossibility of his taking part henceforth in the activities of life or of doing any productive work. He is thus sad, depressed, sometimes melancholy, and voluntarily keeps away from others. Impressionable to excess, weeping readily, often irascible, he becomes irritated without cause or whenever he is called upon for renewed effort or to express his desires a second time.

From the physical point of view, the subject of commotional shock is esthenic, always fatigued, and he confines his movements to the minimum. More often he has headache, giving him the impression that he has "lead in his head" or that his "head is going to burst," and this seems to have much to do with the physical and mental inertia. Furthermore, he almost always has atttacks of vertigo, and the sight may suddenly become dim or fail entirely; the patient feels as if his "head were empty" or his "legs were in cotton," his whole being seems to be fading away, and he has the sensation of nothingness. This lasts for but a second and usually the patient does not fall.

Sleep is always difficult, troubled, and interrupted by nightmares, by hypnagogic hallucinations and long periods of insomnia. It seems as though the return of cerebral activity was at first altogether nocturnal. The tendon reflexes are often active, sometimes greatly exaggerated, but without any epileptoid trembling, and there is sometimes a certain tendency to contracture, an incomplete Kernig's sign, and stiffness of the neck. The stiff attitude and manner of walking of certain patients, "as if they were afraid of breaking," is due to the stiffness of the neck and to the slight but more generalized contracture, to headaches, fatigue, and sometimes to the general pains that every movement provokes, and finally to the inertia of the patient. The pupils are moderately dilated, quite often widely so, and react feebly to light. The pulse often continues slow for several months and the arterial tension is low.

Emotional Shock.—The great majority of subjects of emotional shock return to the front cured without ever reaching the zone of the interior. Grave and persistent postemotional troubles are comparatively rare, if we put aside the hysterical manifestations which are superadded. However, we sometimes see persistent modifications of the mental or moral condition. These are seen especially under two forms which are sometimes either associated or consecutive and which may be distinguished under the titles "emotive neuroses" and "emotive neurasthenia." *Emotive neurosis* may be regarded as a prolongation or usually an amplification the physiological phenomena which ordinarily accompany emotion. It is a condition of persistent and permanent anxious emotivity. "The subject who was brave becomes a poltroon," he has fallen from his state of warrior courage; he is suffering from, so to speak, emotive anaphylaxis; he is a moral invalid. The muptiple phobias, obsessions, disturbances of attention and memory which often lead to flight and sometimes to suicide are the essential characteristics of this anxious, hyper-emotivated, and pathological cowardice. These mental troubles are accompanied by a whole series of psychic, vasomotor, secretory, sensory, and motor troubles—hot flushes, sweating, dermographism, temporary edema, headache, disseminated neuritis, hyperesthesia, tremors, sometimes painful spasms, vertigos, attacks of syncope, etc. Under these physical troubles there is one which is especially constant and that is permanent tachycardia, a trouble which gives to the emotive neurosis one of its essential and distinctive characteristics for it belongs neither and that is permanent tachycardia, a trouble which often irritable, sometmes arrhythmic, and always very unstable, beats between 90 and 110, sometimes 120, and rarely 140, and that for months at a time. There is often arterial hypertension, although, as we have seen, the subject of commotional shock suffers rather from hypotension. The association of this emotivity, of these vasomotor troubles, of the tremors and tachycardia, gives to a number of these subjects the more or less evident appearance of subjects of Graves' disease, and certain authors have seen the complete syndrome of Graves' disease follow a strong emotion. The duration of the emotive neurosis is always long; it lasts months and years and it is kept up and aggravated by repetition of the emotions, and it cannot be influenced, as are hysterical manifestations, by suggestive psychotherapy.

Emotive neurasthenia is less the consequence of violent emotions than of a series of little fatigues—incessant little emotions of life at the front and even more of the simultaneous worries and anxieties regarding family life and those left at home. It does not differ essentially from ordinary neurasthenia and like it is characterized by a sensation of asthenia, rather than by true asthenia, and a sensation of incapacity for acting and thinking, by affective incapacity and loss of initiative, often by nosophobic and hypochondriac manifestations. On the physical side disturbances of nutrition, emaciation, and hypotonia are almost never wanting. It is almost always on this debility of neuasthenia that the prolonged, anxious hyperemotivity of the emotive neuroses develops. When taken in time and treated by quiet and rest, the emotive neurasthenia subsides rapidly and favorably, but it is very liable to relapse.

We have thus endeavored to distinguish the clinical pictures of commotional and of emotional shock

at different periods because, although in practice they are sometimes confused, they are in their pure state perfectly dissimilar and only lack of attentive analysis can confound them. It is also because the prognosis in the two cases is different and consequently the medicomilitary decisions must differ, since true commotion presupposes an organic lesion under the form of dislocation of the nervous elements of a clipping of the noble elements and rupture of their connections—an organic lesion which does not appear to be associated with emotional troubles; because commotional shock, much more than emotional taints the future for a longer time and, finally, is because the immediate treatment of commotional and emotional shock follows different indications.

If at the beginning the subject of commotional shock is inert, the man with emotional shock is fatigued, for one as for the other, stimulants are indicated, although to a very different degree—a necessity for the one, an advantage for the other. Camphorated oil especially, and caffein and ether if needed; warm drinks and general warming of the body.

But afterwards the indications may change and while for the subject of emotional shock the correct treatment will consist in the moral influence, immediate and energetic, which the physician must exercise upon the failing will of the patient, for the subject of commotional shock there will be a question of the opportuneness of lumbar puncture. The subjects of commotional shock have in general a marked cerebrospinal hypertension and, if their condition remains serious, a very slight lumbar puncture, repeated if necessary, will often have a most favorable and decisive influence. We have purposely omitted all reference to hysterical manifestations. Such are in our view only superadded elements often related to emotion as, for instance, the retrospective emotion of the subjects of commotional shock, but also different from the picture of pure emotional accidents as well as from that of commotion. These accidents, the noisy and impressive character of which is disproportionate to their real importance, are well known and the war has not given them any special characteristic aside from their frequency and their sometimes more or less military "tinge." These accidents are amenable to persuasion and suggestive psychotherapy by which they ought to be always rapidly and perfectly curable. They ought in no way to aggravate the prognosis, nor to influence by themselves alone a medicomilitary decision which grants reform or a bonus. It is, however, quite the opposite in case of prolonged manifestations of either commotional or emotional shock.

Medicolegal Notes.

Physician and Surgeon's Accident Insurance.—In an action on an accident policy of insurance over the life of a physician and surgeon two questions were presented: (1) Was the insured at the time of his death "engaged in the occupation of a physician and surgeon"? (2) Was his death effected wholly by "accidental means"? By a stipulation of facts between the parties it was agreed that the insured was at the date of the policy a resident of Walsenburg, Colorado; that at that time his only occupation was that of a physician and surgeon, and that his duties were fully described as those of "general practice"; that he continued in the general practice of medicine and surgery in and about Walsenburg; and that on the morning of the day of his death he called professionally and rendered professional service to several of his patients in the vicinity of that town. He was, at the date of the policy, a surgeon in the medical corps of the Colorado National Guard, and continued to be such until the time of his death, at which time he held the rank of major, and was performing the duties of a surgeon in the medical corps; and all that time he was a member of the American Red Cross Society. On the morning of his death, after visiting a number of his patients professionally, he went with a detachment of 30 men to a point a few hundred yards from the city, the force having been sent out to reconnoitre and resist, if necessary, the activities of strikers who were in the foothills or mountains near the town. The lieutenant of this force was wounded. The insured had just finished dressing his wound, and was down on his hands and knees in a railroad cut observing some men through his field glasses, to decide whether they were strikers or soldiers. He was shot, and died almost immediately. It was held that, at the time of his death, he was engaged in the occupation of physician and surgeon. To the contention that he had changed his vocation, the court said that his service with the company was only temporary. He was called out to meet an emergency. While the service lasted for some months, it was merely a side issue. It was known that it would be temporary, and was to be considered as answering a call to suppress a riot, or any other temporary engagement. Moreover, he was not engaged in the military activities of his company. His services there were those of a physician and surgeon. He continued to practice his profession generally as well as to attend to the needs of his company. The authorities are uniform that such temporary changes do not constitute a change of occupation within the meaning of insurance policies. To constitute such a change there must be an abandonment of the vocation specified in the policy and the adoption of some other calling. If such temporary activities as those of the insured are to destroy the protection of insurance, it must be by an express provision of the policy.

It was held, on the question of whether the death was accidental, that whether his death was intended by the person who fired the fatal shot, which was matter of conjecture, was immaterial. As to the deceased the death was accidental within the meaning of the policy.—Interstate Bus. Men's Acc. Assn. v. Lester, 257 Fed. 225.

Infection Through Skin Puncture.—An insured under an accident policy punctured a pimple with an infected scarf pin, in ignorance that the pin was infected Infection was immediately communicated and spread, causing his death. In an action on the policy it was held that whether the death be ascribed to the original injury under the doctrine of proximate cause, or whether the infection be deemed a part of the injury, the case was governed by a clause of the policy providing that whenever, as the direct result of an injury occurring solely by external, violent, and accidental means, the skin is punctured, and there is introduced into the system through the puncture and by the same means causing the puncture, any bacteria which shall produce blood poisoning or infection, indemnity for disability or death resulting therefrom shall not exceed $500. Interstate Bus. Men's Acc. Assn. v. Lewis, 257 Fed. 241.

Harrison Act—"Preparations and Remedies."—In a prosecution for violation of the Harrison Act the Circuit Court of Appeals, Sixth Circuit, holds that the words "preparations and remedies" contained in section 6 of the act are not meant to include clear morphine, but relate to actual medicinal "preparations and remedies which do not contain more than one-quarter of a grain of morphine"—such preparations or remedies as a druggist or physician would normally dispense. In view of the fact that the defendant was not charged as a physician or a druggist, he was held sufficiently informed of the accusation, and that under that accusation it was open to him to show that he was merely dispensing medicinal "preparations and remedies" containing not more than the permitted amount of morphine.—Stetson v. United States, 257 Fed 689

COMPULSORY HEALTH INSURANCE AND CLASS CONSCIOUSNESS.

THE imperial message (allerhöchste Botschaft) which Prince Bismarck addressed to the Reichstag on November 17, 1881, outlined in a preamble the proposed schemes of Social Insurance, the chief of which was Health Insurance, for the "laboring classes," and concluded with the following sentence: "This more intimate association of the government with the laboring forces of the Empire and the combining of these into the form of corporate Trades Unions under government protection and under government control will, we hope, make possible and aid in the solution of national problems that could not otherwise be solved by even the vast powers of the State unaided by these measures."

There were no problems of a concrete or corporeal nature in the lives of the people that an arbitrary absolutism such as then was the imperial German government, could not control by governmental powers alone. But democratic tendencies of an individualistic character manifesting themselves to a dangerously increasing degree among the laboring classes threatened the sole and absolute empire of the State. These tendencies had been growing ever since the victorious war of Germany with France in 1871.

Education of the laboring people as a result of the war was threatening, however concealed in its manifestation, absolutism and seeking expression in democracy. Bismarck knew it and hoped to negative these strivings by the gift, in reality the bribe, to the laboring classes of compulsory health, accident, old age, and invalidity insurance under governmental aid and control.

These bribes given under the guise of altruism had for their most important function the suppression and crushing of the democratic instinct in the hearts of the German laboring people. In our own country the altruists and philanthropists, taking Bismarck's altruism seriously, ignorantly propose compulsory health insurance, overlooking the fact that the governmental paternalism at the basis of and fundamental to compulsory health insurance would be destructive of the individualism absolutely essential to democratic principles and democratic institutions. Compulsory health insurance was necessary to crush the strivings toward democracy amongst the German people; compulsory health insurance would be destructive to established and successful democracy in our own country and amongst our own people. Class consciousness is inimical to democratic institutions—create classes and the classes create for themselves their own tyrants who arise at the points of least resistance, first as leaders and arbitrators and at the favorable moment as absolute dictators.

The venom of class consciousness is threatening those who are ignorant amongst the manual workers of our country today, and compulsory health insurance would be a great factor in bringing to a focus that threat. From the standpoint of the educated physician such schemes of compulsory health insurance, by enormously increasing the struggle for his economic existence, develop class consciousness and union with his fellows to prevent the confiscation by the government of his mental and physical energies to be given as an altruistic bribe to the politically more powerful laboring classes. For the confinement and control of these latter in their classified cells compulsory health insurance would be an important factor. This act would thus not only solidify class consciousness amongst the manual workers but would add a new class in its turn to be solidified under the stress of self-protection amongst the most intellectual of the community, the doctors of this broad country.

That this class consciousness of the doctors of the German empire has resulted from compulsory health insurance is partly shown by the following facts: Compulsory health insurance lowered the economic standing of the medical profession and its practitioners because:

1. The burden of compulsory health insurance rests upon and is to a great extent at the expense of the doctors' income. The combined amount charged and paid for health insurance by the employer, employee, and State as compared with the cost of the benefits to which the insured are entitled, apart from medical and surgical services, is so large that little or nothing is left with which to pay the doctors. A vast amount of medical work had to be done by the individual doctor practising under compulsory health insurance with only a small return in fees or salary. The hardship of this was not apparent to the public, for people were accustomed to see medical work done for little or nothing in connection with philanthropic or altruistic endeavor. The government took pains to represent compulsory health insurance as an altruistic movement and to aid in its success was considered at first a patriotic duty.

2. The physician's economic status was further affected by the fact that so large a percentage of the population was insured under the compulsory health insurance act, that the field for private practice became very much restricted. This limitation increased with every change in the law, which admitted to the advantages of compulsory health insurance those with a larger earning capacity. Thus in 1882 for every 1,000 of the population 114 were not entitled to compulsory health insurance, but this number diminished until in 1907 only 89 per thousand were not insured (Ewald). These few

private patients naturally gravitated to the wealthier and better known physicians while the condition of the average practitioner rapidly degenerated into impoverished slavery and serfdom to the public. Amongst men such as these there can be no progress toward the enhancement of the science of medicine. The fight for existence preoccupies every faculty.

Where funds preferred to hire their doctor upon an annual salary basis, the same economic difficulties occurred. The salary was and is far below a living wage, the amount of work is prohibitive, and the quality of the medical attention is of the lowest. This type of medical work does not, and did not, insure health even when the health insurance is compulsory. Governmental edict cannot change black to white or bad to good. These medical difficulties would have prompted the funds to pay more but the wherewithal was not so easily obtained. It was found that the employees and employers combined would not pay more than 4 per cent. of the salaries of those insured, out of which funds all of the benefits under compulsory health had to be paid. Any larger tax resulted in grumbling on the part of the workers and the employers. That would disturb the acquiescent trance into which the boon of compulsory health insurance had thrown the German people. The physicians were politically least important and they were kept at the yoke by a policy of appeal to their patriotism and their self-respect and small occasional increases in their fees.

But even in Germany this destructive policy in the treatment of the practitioners of the most indispensable and most learned of the professions resulted in the alienation of the good will of the members of this profession who were and are in constant strife with the officials in charge of the funds owing to their despair at earnings insufficient for a livelihood. In addition a laudable indignation at the constant and frequently ignorant supervision of lay and professional officialism to which the medical practitioners under compulsory health insurance were subjected, and the ingratitude of their patients, who, being under no direct pecuniary obligations to the doctors of the fund, looked upon them as a part of the vast espionage system of the government—all of these things resulted in a lowered social standing of the profession. Gone was the native dignity of the doctor. It was inherited from doctors who went before him and instilled in him from the very beginning of his medical career. The doctor thus endowed was ennobled by the supreme importance of the duties entrusted to him by society, for even his professional servitude "kept alive" "the spirit of an exalted freedom." Compulsory health insurance changed all this. You can not make the right kind of doctors out of impoverished slaves.

So that class consciousness created by German absolutism to bind and control the "classes" who labor with the hands, and class consciousness produced as a by-product in the compulsory socialization of the medical profession, were both the results of compulsory health insurance. Both of these two types of "class consciousness," the laborer's and the doctor's, could be used for the government and control of these two "classes" of human beings only under and with the aid of the conditions present in a government of monarchical absolutism such as that of Germany.

It would not be effective under our democratic institutions. For in a republican democracy even the creation of "class consciousness" in important classes of the people tends to undermine the spirit of individualism which is basic for democracy; such "class consciousness" and its results can be effectively maintained only by the arbitrary methods possible under none but autocratic rule.

This should be apparent to the imitators of German compulsory health insurance in the United States whether the object they have in view is a blundering philanthropy to, and pauperization of the manual workers, or whether they, few in number we hope, deliberately plot to destroy democracy in America. Only a few years ago most of us would have even doubted the existence of such plotters, however few, but the costly knowledge gained through the war has changed all that. While we still believe that the vast majority of the proponents of compulsory health insurance are such in ignorance that the very essence of liberty and democracy is at stake, yet it is a fact that such destruction of democratic institutions will inevitably occur as a result of the establishment of compulsory health insurance and the changes of our institutions and laws necessitated thereby.

A study of the German development of compulsory health insurance shows the necessity and application of methods destructive of even a semblance of the democratic and individual rights of the people. Even the German people paid dearly for the "gift" although they had incomparably less than we to lose in the way of individual liberty; for personal liberty was only a word without meaning to the German subjects long before compulsory health insurance was established. The soil for the confiscation of the few liberties left to them was prepared and ready, and the plant "Compulsory Health Insurance" grew luxuriantly in such a soil. The working people were accustomed to surveillance and espionage on the part of the government. The inspector with the little book and pencil was no stranger to them. Under the necessities of governmental control for compulsory health insurance he kept accurate accounts of every man's employment and wage—his employer, the days he worked and the days he wasted, the days he was ill or claimed to be ill, what he ate and what he drank, the medicines he took, the tobacco he smoked, his life history and his body inheritance, when he left his job and why, how much he saved, how much he spent and for what; things that he dared to think but scarcely knew, things that were known only to himself and his Creator, the government wished to know and finally knew.

The employers too had no secrets from official compulsory health insurance. How many men they employed, their names, their working hours, the amount, quality, and value of what they produced, how many they had hired, how many they had discharged, and why, the increased cost of the product, owing to the cost of health insurance, and many other similar questions, *ad infinitum, ad nauseam*. Each year a new, more efficient official wished a new line of facts. "First one vulture

then another until the air was black with pinions." For the object of the government was to achieve "the solution of national problems that could not otherwise be solved," such as absolute control of the working population through compulsory social insurance.

Facultative or voluntary social insurance, including health insurance, not connected with the State, groups of people have had for centuries in most countries. This type of social insurance has nothing in common with compulsory social insurance, if for no other reason, for the single fact alone that when voluntary social insurance becomes objectionable the people themselves can drop it. Compulsory health insurance under State auspices ostensibly created for the welfare of the people and the stability of the State, like another Frankenstein monster turns upon its creators and undermines and destroys them.

Little more can be said within the limits of this editorial article. But a study of this subject will lead us to the conviction that compulsory health insurance is a typically German product, requiring governmental control of the German type for its malign development. That to introduce it into a democratic country such as ours inevitably will result in restriction of our liberties, diminution of our efficiency as a people, and cessation of our progress which heretofore has been the admiration of civilization.

So far as the profession of medicine is concerned compulsory health insurance will be followed by a lowering of social and scientific medical standards to those attractive only to an intellectually lower grade of men. It will destroy ideals of scientific advancement. It will tend to replace in the minds of its practitioners as a class high moral ethical precepts by the individual selfishness enforced by conditions involving a dread struggle for existence.

AN UNUSUAL CASE OF MYOSITIS OSSIFICANS.

The incidence of myositis ossificans following traumatism is not rare, but it is rare to have two patches develop from two separate traumata of the same quadriceps extensor femoris, all within a few weeks. A case of this sort has recently been reported by Capt. Geoffrey Jefferson in the *British Journal of Surgery*, July, 1919, vi, 23. His patient was kicked by a horse May 23, 1918, and at the site of contusion of the front of the left thigh marked swelling developed, and caused great disability which persisted to a greater or lesser degree up to the time when he received a second injury to the left thigh. On July 9, a little over six weeks after the first injury, he fell and struck heavily on the left knee. The knee quickly swelled and he could walk only with great difficulty; so he was soon sent to the base hospital. A swelling of bony hardness was then noted deep in the extensor muscles at the middle of the left thigh, and *x*-ray plates showed this to be a plaque of myositis ossificans which had developed at the site of the original injury. Later the *x*-ray also showed a plaque which had developed at the site of the second injury.

In the same journal, J. W. Geary Grant reports a case of progressive myositis ossificans and well states the grounds for and against operation in such cases. His patient was a girl 4 years of age who had a typical case of myositis ossificans progressiva. There were plaques situated in various tendons of the erector spinæ muscles, the latissimus dorsi, pectoralis major, and teres major. The arms were adducted to an angle of 15 or 20 degrees from the chest and firmly fixed in that position; while the scapulæ were also fixed to the chest wall. There was also a peculiar deformity of the thumbs and great toes, which has been found in 75 per cent. of the recorded cases of this type of the disease, and which consists in deformity associated with absence of the proximal phalanges and a malformation of the heads of the metatarsals and metacarpals. Grant operated upon this case merely to put the arms in a more useful position. When seen some months after operation the plaques of bone had reformed but there was still abduction to an angle of 45 degrees. However, he says: "At the same time I may frankly say that I do not think the operation worth doing. In every recorded case excision of the bony masses has been followed by recurrence." On the other hand, his experience in the cases of traumatic myositis ossificans, like that of many other operators, has been very happy, as there is usually a good functional result with little or no tendency to recurrence.

SYPHILITIC CIRRHOSIS OF THE LIVER.

For many years the question of venous cirrhosis of the liver has been much mooted and has been the object of interesting researches. Alcoholism was at first looked upon as the *primum movens* of these organic changes of the liver, but during the lapse of half a century its part as a casual factor has progressively diminished in the estimation of the profession. As early as 1840, Becquerel had shown that hepatic cirrhosis could and did follow a cardiac lesion and then Frerichs referred to the part played by syphilis and malarial infection in the production of the morbid changes in the liver. In 1869, Lancereaux, taking the etiology of the affection as a basis established a classification in which alcoholism, syphilis, and paludism are considered as the three great factors of the lesions of hepatic cirrhosis. This classification, which at first sight is pleasing, does not always correspond to the reality of facts observed—and it has been demonstrated by Balland (Thèse de Paris, 1912) that clinically a close resemblance exists between syphilitic and alcoholic hepatic cirrhosis and that errors in diagnosis are easy to make.

The vast group of the alcoholic cirrhoses has been still more restricted. Jousset has shown the important part played by the bacillus of tuberculosis in the so-called alcoholic cirrhosis of the liver and there is no reason to suppose that the *Treponema pallidum* is unable to produce injuries to the hepatic cell analogous to those produced by alcohol. Its morbid action on the liver of both children and adults, either by its presence or through its toxins is too well known to require description here, but the point upon which emphasis must be made is that syphilitic cirrhosis of the liver frequently clinically simulates the alcoholic forms.

Debove has insisted on the very considerable part played by the *Treponema pallidum* in various organic morbid processes, and Castaigne has well said that a known or unrecognized syphilis is often the causal factor of affections which were formerly supposed to have no relationship whatsoever with this disease. Therefore, it is incumbent upon the physician to go minutely into the hereditary and personal antecedents of all patients presenting a cirrhosis of the liver the nature of which gives rise to any doubt, and also to resort to all clinical procedures which may lead to a precise diagnosis.

The Wassermann test will of course give information of value, and the therapeutic diagnosis, based upon the results of antisyphilitic treatment, will, in those cases where syphilis is suspected with reasonable certainty, confirm or disprove the supposed causal factor of the cirrhosis.

Whale Septicemia.

Writing in the *Norsk Magazin for Lacgevidenskaben* (October, 1919, lxxx, 10), Christiansen states that from as far back as the Middle Ages to near the present time certain whalers on the western coast of Norway have caught whales by first poisoning them with infected arrows. The animals rapidly became exhausted and thus became an easy mark for the harpoon. In the 80's of the last century Hansen and others isolated the bacillus believed to be responsible for this affection. This mode of fishing has been superseded, but muscular tissue from whales thus infected still exists in the Copenhagen Veterinary Serum Laboratory and although 30 years old it has been possible to cultivate from it the whale bacillus and study the latter by modern standards. It is evidently closely related to the Ghon-Sachs group and congeners, several of which are well known causes of disease in domestic animals. It is peculiar in being immotile and unprovided with flagella, while it is much slower in liquefying gelatin. It is further more apt to form spores in the organism infected. Cultures have been found to be highly virulent to many small laboratory animals. Poultry have much immunity but a porpoise died within 24 hours after inoculation. The lesions at the point of inoculation include edema, hemorrhage, extensive muscle necrosis and degeneration. To go more into detail this method of whale fishing can be traced back to the 12th century but was apparently limited to a small stretch of coast near Bergen, at which point the animal used to enter a bay known as Kvalwaag. Moreover a particular species of whale, *Balænoptera rostrata,* seems to have been the only sufferer from this mode of catching. It is a rather small whale which attains a length of about 30 feet. Hence the method, an extremely primitive one, never came into general use but obtained only under very special conditions. In the absence of definite information we may assume that the poison was obtained from the muscle of dead animals killed by this method. We may also assume that whale septicemia was a disease to which the animal was subject before the practice came into vogue.

News of the Week.

Hospital Installs Group Practice.—Dr. Otto V. Huffman, dean of the Long Island College Hospital, announces that a group of experts has been organized among the hospital and dispensary staff of the institution which will receive any cases referred to them by any alumnus of the hospital, and will give examinations, diagnosis, and advice in regard to such cases. This service will be rendered to patients for an ordinary fee and in many cases without the payment of a fee. In each case the diagnosis will be made by a specialist and all cases will be passed upon by the medical and surgical staff. For the present these services will be extended to alumni of the hospital only.

Tuberculosis in the Army.—A recent report of the Bureau of War Risk Insurance shows that of 27,314 claim cases filed with the bureau, tuberculosis is the greatest single cause of disability, constituting 22 per cent. of the whole. Wounds necessitating amputation of the limbs total only 5 per cent., while wounds not necessitating amputation and miscellaneous wounds of all kinds total 31 per cent. Nervous diseases and disorders are 8.3 per cent. The figures for these disabilities on the preceding report were: tuberculosis 30.8 per cent.; wounds requiring amputation, 3.2 per cent.; wounds not requiring amputation, 7.9 per cent.; nervous diseases, 9.6 per cent.

Work of the Red Cross Splint Department.—A recent Red Cross bulletin describes the work of the Splint Department, which when the army went overseas agreed to supply splints. The army placed with the organization an order for 462,350 splints, and of this number 294,583 were shipped before the signing of the armistice. The largest order given by the army during one month was placed in August, 1918, and was for 535,999 splints. There were 205 tons of steel used in the manufacture of these splints. The American Red Cross also attended to all the storing and shipping of these supplies.

Dr. Hugh Cabot, professor of genito-urinary surgery at the Harvard Medical School and chief surgeon of the genito-urinary service of the Massachusetts General Hospital, has accepted the appointment of chief surgeon at the University of Michigan and expects to enter upon his new duties about the first of the coming year.

Dr. Ernest L. Hunt of Worcester, Mass., has been appointed Director of the Surgical Service and Dr. Edward B. Bigelow Director of Medical Services at the Worcester City Hospital.

Dr. Dudley Roberts has removed his office to 270 Park Avenue, New York.

Dr. J. Ramsay Hunt has removed his office to 46 West 55th Street, New York.

Dr. Edward Wallace Lee has been discharged from the medical service of the United States Army and has resumed his private practice at 616 Madison Avenue, New York.

Dr. Charles H. Goodrich has resumed his practice at 280 Park Place, Brooklyn, N. Y.

Dr. John Edward Jennings has resumed his practice at 23 South Portland Avenue, Brooklyn, N. Y.

Dr. William C. MacCullum of Johns Hopkins University and his assistant, Dr. John R. Paul, who have been doing medical research work in Peru, have returned to the United States.

Dr. Charles Kohly of Cuba has arrived in New York where he will remain for about a month.

Fight Against Yellow Fever Apparently Won.—Major-General William C. Gorgas, on his arrival in Panama, on October 4, reports that yellow fever has been practically eradicated from Guayaquil, Ecuador, and that with this achievement yellow fever may be considered to be banished from the earth, as Guayaquil was the last large centre where yellow fever was endemic. No cases of yellow fever have occurred at Guayaquil for several months, and if there is no outbreak during the coming rainy season the sanitary measures instituted may be considered effective.

A Pitfall for the Unwary.—A man representing himself as a physician is canvassing among doctors with an electrical diagnostic set on which he collects a deposit, promising to deliver the apparatus within five days, but it is never delivered. The man poses as coming from Springfield, Mass.

Obituary Notes.—Dr. Henry August Dodin, a graduate of Bellevue Hospital Medical College, in 1882, died at his home in New York City, on October 1, aged 61 years.

Dr. A. Reginald Karreman of Chicago, a graduate of the University of Michigan Medical Department, in 1888, and of Rush Medical College, Chicago, in 1889, was murdered in his home, on September 30. He was 51 years of age.

Dr. William A. De Long, a graduate of New York University Medical College, in 1863, died after a brief illness at his home in Brooklyn, N. Y., on October 3, aged 79 years. Dr. De Long was for twenty years medical officer of the Fire Department of Brooklyn. During the Civil War he served as assistant surgeon of the Seventy-seventh New York Volunteers.

Dr. Joseph Henry Reuss of Cuero, Texas, a graduate of the College of Physicians and Surgeons, New York, in 1889, died suddenly in Houston, Texas, on September 17, aged 52 years. He was head physician of the San Antonio and Aransas Pass Railways and recently completed a new hospital at Cuero.

Dr. Ira E. Chase, a graduate of the Berkshire Medical College, in 1852, and of Jefferson Medical College, Philadelphia, in 1853, died at his home in Haverhill, Mass., after a prolonged illness, on September 23, aged 88 years.

Dr. Charles Martin Troppmann died suddenly at his home in San Francisco on September 20, aged 56 years. He was a graduate of the College of Physicians and Surgeons, San Francisco, in 1900, and a member of the faculty of that institution at the time of his death. He was also prominent in fraternal circles.

Dr. William Lee Dalby, a graduate of the Medical College of Virginia, in 1891, died of Bright's disease after a protracted illness, at his home in Bridgetown, Va., on August 14, aged 54 years.

Correspondence.

MENINGITIS FOLLOWING LUMBAR PUNCTURE.

To the Editor of the Medical Record:

Sir:—Having read carefully the article referred to in your editorial, "The Dangers of Lumbar Puncture," which appeared in the Medical Record for September 13, I think that you may have inadvertently misunderstood the authors' conclusions. They only advised specifically against lumbar punctures in the absence of signs of meningeal irritation. Moreover, the number of cases (5) in which lumbar puncture was followed by the development of meningitis was too small to establish a definite "propter hoc" relation between the procedure and the event. Of course when a sepsis is present there is always a possibility of a meningitis developing and when a meningococcus sepsis is present the development of a meningitis is extremely probable. Three of these five cases belonged to this class.

Dr. W. W. Herrick in his admirably studied series of cases at Camp Jackson (where the authors referred to also carried out their studies) combined lumbar puncture and the administration of serum intradurally as well as intravenously in all cases, even before the appearance of meningeal symptoms.

During the past nine years the members of the Meningitis Division of the Research Laboratory of New York City have performed more than 500 lumbar punctures to make the diagnosis or to relieve the symptoms of meningeal irritation in cases that were thus proved not to be meningitis. In only two instances have cases of meningism, in which lumbar punctures were done, been followed by a real meningitis, and in one of these cases so much time (nearly two weeks) elapsed between the performance of the lumbar puncture and the development of the meningitis that it does not seem probable that there would have been any connection between them, even granting that such a connection may exist. It seems to the members of the meningitis division highly improbable that there is any real danger of a meningitis being produced in this way in view of the two facts—the rarity with which a lumbar puncture resulting in a normal fluid is followed by meningitis, and also the fact that the rather large number of cases of purulent meningitis that we have seen have developed without being preceded by a lumbar puncture, with the two exceptions noted above.

Cases of pneumonia with signs of meningeal irritation are frequently seen. In these cases it seems to us very undesirable to delay the lumbar puncture because the symptoms may be due to an epidemic meningitis occurring with the pneumonia, not to a meningism or to a pneumococcic meningitis secondary to the process in the lungs. In the first of these possibilities it is of the greatest importance that serum treatment be instituted early; in the second possibility, that of a meningism, it has been our experience that the withdrawal of fluid is followed, in the majority of cases, by a very prompt relief of the symptoms; and in the third

possibility, that of a pneumococcic meningitis, the diagnosis is established.

While we do not advocate the performance of a lumbar puncture in the absence of meningeal symptoms or some well-defined indications for it, the danger of delay in cases where it is indicated is so great that if there is a question as to its desirability it is better to err on the side of safety in performing an unnecessary lumbar puncture, rather than to defer one that is needed. It is abundantly proved by the statistics of others and our own experience that a delay in lumbar puncture and consequently in making the diagnosis and instituting serum therapy results in a higher mortality in epidemic meningitis or in a longer and more tedious course.

In view of all these considerations we feel that, instead of being restrained, physicians should be urged to resort more freely to a procedure which, when carefully done, is attended with so little risk, and yet is of so vital importance in diagnosis and treatment.

Josephine B. Neal, M.D.

Meningitis Division, Bureau of Laboratories, Department of Health, New York City.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, Sept. 19, 1919.

Meeting of the British Association.—The meeting of the British Association was held this year at Bournemouth, a very delightful watering place on the south coast. The meeting opened on Sept. 9 and was well attended. Many papers of medical interest were read. Among these was one by Dr. F. G. Parsons in the anthropological section.

On the racial character of the modern Briton, he pointed out that there was still much difference of opinion as to whether or not the cranial index was a valuable clue to racial origin. There was a great weight of opinion in favor of the belief that there were three major racial types in the population of modern Europe, the Nordic, the Mediterranean and the Alpine. The latter was distinguished from the two former by a higher cranial index, that is to say, by the possession of a rounder head. The value of the distinction, as well as of others, such as the orbital index, which has been used to distinguish the Nordic from the Mediterranean, the value of stature, of eye color, and of hair and skin color, were all more or less in dispute. For his part, he held the view that the cranial index was the most satisfactory test. He laid stress on the contrast between the typical German population and that of the British Islands. Although there were a certain number with round heads in Great Britain, the modern Britain had on the average, the lowest cranial index in Europe. The Germans were typically round headed. This fact had long been suspected, but the Germans, in association with their Pan-German views, had refused to collect or to publish the evidence which showed the true state of affairs. Methodical examination of German prisoners of war which Dr. Parsons had been allowed to make revealed that even in Schleswig-Holstein the Germans were round headed. So far as psychological character could be associated with cranial characters he believed that the round head was slow, methodical and unwilling to take risks and that the long head was adventurous, enterprising and imaginative. In the same section Professor Arthur Keith discussed the origin of the racial types into which man is divided. Although the evolutionary machine as it is commonly understood does not supply a clue to the origin of the European, the Chinaman and the Negro, Nature has at her command a secret mechanism by which she works out the new patterns in the bodies of man and beast, a mechanism of which we were almost ignorant in Darwin's day, but which we are now beginning to understand dimly. There are five small glands which in recent times have come to be recognized as parts of the machinery which regulate the growth of the body. These are the pituitary, the pineal, the thyroid and the two suprarenal bodies. The influence of the thyroid on the growth of the skull and skeleton was profound. The root of the nose appeared to be flattened and drawn backwards between the eyes, the upper forehead projecting and bulging, the face flattened, and the bony scaffolding of the nose, particularly when compared with the prominence of the jaws, greatly reduced. Now these facial characteristics gave the Mongolian face its characteristic aspect, and to a lesser degree were also to be traced in the features of the Negro. Professor Keith set forth the evidence which led him to believe that the pituitary body was specially concerned in the differentiation of the European or Caucasian. He pointed out that the sharp and pronounced nasalization of the face, the tendency to strong eyebrow ridges, the prominent chin, the tendency to bulk of body and height of stature in the majority of Europeans are best explained, so far as the present state of our knowledge goes, in terms of pituitary function. The interstitial cells of the testicle are also concerned in the production of the robust manifestations of the male characteristics found conspicuously in the Caucasian type. In both Mongol and Negro a beardless face and almost hairless body are associated with removal or degeneration of these glands.

Industrial Overstrain.—Dr. C. S. Myers in an address to the Psychology Sub-section took as his subject industrial overstrain and unrest. He said in part that the most important and most dangerous source of fatigue lay in the highest levels of the central nervous system which were concerned in self-effort. Self-effort tired as a preventive against local exhaustion. Boredom was its earliest warning sign. The monotonous application for relatively long hours at light work induced a central incapacity even more serious than employment for shorter hours at more strenuous muscular work. In heavy monotonous muscular work the spinal cord automatically inhibited the efficiency of the self in contracting muscles involved. In monotonous mental work the continual conscious effort to inhibit incompatible evil mental processes rapidly led to a weakening of higher control and ultimately to the appearance of overstrain. The emotional experiences of the past and present remained no longer under control. Old anxieties, hitherto successfully repressed, escaped from their previous banishment into the unconscious. There was a shortage both of physical and psychical stor-

age capacity. From such various causes the prevalent industrial signs of slackness, distrust, suspicion, irritability and defiance had developed. Employers and employees had much to reproach themselves in this respect, and in their attempts to escape the consequences of self-depreciation fixed the blame on each other. Professor Myers pointed out that such were the fruits we were now reaping after the strain of warfare and stated that certain steps should be taken in order to prevent their recurrence in the future. In his opinion five measures were needed: The first was the proper regulation of hours of work and rest in different industries according to the nature of the occupation; and the reduction, as far as possible, of the monotony of work by augmenting the worker's interest, knowledge and sense of responsibility by varying his work and by carefully selecting workers who were not innately desirous of variety of occupation. There must also be the establishment of a whole-time industrial medical service of physicians specially trained in the psychological and physiological conditions governing the workers' welfare, and provided with executive as well as with advisory powers. A National Institute of Psychology and Physiology applied to industry and commerce must also be established. A scheme to this end had been prepared and financial support was invited. Dr. Myers also suggested the establishment of post-graduate university diplomas in industrial medicine as a qualification for medical officers engaged in the work and the provision of clinics and sanatoria throughout the country where cases of functional nervous disorders arising from overstrain in civil life might be treated by specially trained and qualified doctors. Such clinics and sanatoria had been established for the treatment of soldiers, but instead of transferring them from the Ministry of Pensions to the Ministry of Health they were allowed to be closed, and many of the medical officers engaged therein compelled reluctantly to resume private practice. As matters stood, there was no provision for the recognition and proper treatment of overstrain in civil life, but unless this deficiency were met one of the most important lessons of the war would not have been learned.

Butter and Substitutes.—Professor W. D. Halliburton lectured on "Butter and Margarine" before the Physiological Section. He remarked that "Give us this day our daily bread" had been our prayer for many years, but "Sell us this week our weekly butter" was a petition of more recent origin. The Germans had suffered from fat shortage more than the British, and their practice of having newspaper articles written to order had been extended into their scientific publications to show that fat was unnecessary and that tuberculous meat could be eaten without harm, but they had not yet succeeded in convincing any scientific body of representative observers of the truth of their arguments. The most striking proof that fat was necessary came from the study of disease, and there was no doubt that much of the disease now rampant in Germany was largely attributable to the absence of fat from their food. There were fats and fats, and although all of them yielded approximately carbonic acid and water and had the same heat value, there were in butter, for instance, subtle materials which had not been absolutely identified by the chemist, substances termed vitamines or accessory food factors. All these came from the vegetable world. When a cow ate grass it showed these products of the vegetable world in its own fat, and passed them out in its milk, and they subsequently passed into butter. Rickets was largely caused by the absence of these vitamines, a very little of which went a very long way. White bread and margarine might make a palatable mixture for those who liked margarine, but brown bread and butter contained the vitamines and should be used in larger quantities. He was afraid that he could not suggest any remedies for the threatened food shortage, for it was just as difficult to get farmers to move as to induce miners to mine coal. He concluded by drawing attention to the fact that margarine had been made extremely palatable, but this did not disguise the truth that it was lacking in vitamines, and some effort should be made to use butter fat, or to insist that margarine should contain a certain proportion of animal fats which contained vitamines. He had been asked what was the best margarine, but he could only say that for eating purposes it was real economy from the point of view of health to buy the most expensive.

It should be said that the meeting just over at Bournemouth was the first meeting of the British Association since 1916.

AN APPEAL FOR HUMAN EMBRYOLOGICAL MATERIAL.

To the Editor of the Medical Record:

Sir:—In 1906 I observed certain malformations of the human shoulder-blade, and in contributions to current literature I have given them the collective name—"the scaphoid type of scapula," and pointed out some of its hereditary, clinical and anatomical significance. Probably the most important observation connected with this type of scapula in man is its age incidence, that is to say, it occurs with great frequency among the young and with relative infrequency among the old. There appear to be two possible explanations of this fact: either (*A*) one form of shoulder-blade changes into the other during development and growth; or (*B*) many of the possessors of the scaphoid type of scapula are the poorly adaptable, the peculiarly vulnerable, the unduly disease susceptible—the inherently weakened of the race.

I have attempted to answer these questions by seeking evidence in various directions and one of the most important of these has been a study of intrauterine development of shoulder-blades. My investigations in this direction have been limited by the material at my disposal, which has been inadequate for a definite solution of this phase of the problem. I am, therefore, appealing to physicians for fetuses in any and all stages of human development.

It is desired that the material, as soon as possible after delivery, be immersed in 10 per cent. formalin in a sealed container, and be forwarded to my address, charges collect. Due acknowledgment will be made to those forwarding material.

1. Diet in Digestive Diseases in Infancy.—J. P. Crozer Griffith discusses briefly the causes and dietetic treatment of acute gastric indigestion, acute diarrhea, acute gastroenteric intoxication, ileocolitis, chronic gastric indigestion, and chronic intestinal indigestion. In *acute gastric indigestion*, whether the cause is mechanical or chemical, the process is an acute one and very largely local. Here the dietetic treatment is simple. No food is administered except barley water, which is no better than ordinary water, but is more satisfactory to the mind of the mother. After the attack has subsided barley water may be continued, or small quantities of albumen water or fat free broths given frequently. A return to the ordinary diet may be made by way of diluted skimmed milk, or rice or arrow-root gruel. The important matter is that there should be no hurry in returning to the ordinary food. In *acute diarrhea* the same dietetic management should be employed as in acute gastric indigestion, having, however, the character of the stools in view. It is particularly important to be slow in getting back to a milk diet when disturbances of the gastroenteric tract are present. *Acute gastroenteric intoxication* is a much more severe type of gastrointestinal disorder, in which in contradistinction to the diseases already mentioned we have the element of decomposition of the tissues due to toxemia. The great desideratum in the treatment of gastroenteric intoxication is not to allow it to occur. The dietetic treatment is similar to that outlined; the return to ordinary food must be very slow. In the meantime it is essential that the infant receive an abundance of water to prevent drying of the tissues as well as acidosis. It is only where the children are already marantic from previous illness that one must be cautious in too prolonged starvation. In the treatment of *acute ileocolitis*, the fact must be borne in mind that this is an inflammatory disease, otherwise the symptoms might lead one to do without food for too great a length of time, on the ground that the child still showed evidences of toxemia. Milk should be entirely avoided at first and possible even throughout the whole attack. As the disorder is one that is always somewhat prolonged it is necessary to see from the beginning that the infant takes sufficient food. For this purpose broths thickened with some starchy substance, and often containing the meat fibre cooked until well broken up, and strong gruels may be employed, and gruels may sometimes be dextrinized with advantage. Albumen water and scraped beef may also be fed, and finally one may return to a milk diet by the use of whey, skimmed milk, peptonized skimmed milk, casein milk, butter milk, and the like. Frequently the food is best administered in small amounts at frequent intervals *Chronic gastric indigestion* is usually a sequel to one or more attacks of acute gastric indigestion from which recovery has not been satisfactory. Various constitutional diseases may also be a predisposing factor. The study of the cause is very important in determining the nature of the treatment, and it is imperative, too, to make sure that some other cause than indigestion is not operative. The most important symptom is usually repeated vomiting. It is important before beginning treatment to exclude other diseases, as pyloric stenosis or vomiting of a nervous nature. As a rule one suspects that the diet is too rich in fats and after this the sugar may be in excess. The protein is usually borne better. First fat should be reduced and for this a buttermilk mixture may be employed. This consists of buttermilk fortified by the addition of wheat flour and sugar in quite considerable amount, raising the total carbohydrate to possibly ten or eleven per cent. If vomiting continues in spite of this good results may be obtained by reducing the sugar considerably. Malt soup mixtures are often serviceable. Some infants exhibit for quite a while an intolerance for milk and in such cases good results may accrue from the administration of concentrated amylaceous gruels and of these arrowroot seems to be particularly serviceable. *Chronic intestinal indigestion* may be associated with chronic gastric indigestion. It may be brought about by bad hygienic surroundings, by a congenital constitutional debility, or may follow an acute ileocolitis. It is important to determine the dietetic causes. The principal symptom is a steadily increasing malnutrition. It is necessary to obtain a very detailed history of the previous life of the infant so far as the matter of diet is concerned. In the dietetic treatment one may begin with a temporary partial starvation, using a thin cereal decoction, or arrowroot water. After this the nature of the diet will be determined to some extent by the stools. If the fat is at fault, buttermilk, casein milk, or skimmed milk, may be employed. Casein milk without the addition of sugar is often serviceable where there is indigestion of sugar as well as of fats. Other factors to be considered are the dilution of the food, frequency of administration, and the mutual influence which various food elements exercise upon each other. Proprietary foods serve no good purpose and contain nothing which cannot be prepared at home.

9. Diagnosis and Treatment of Diseases of the Gallbladder and Biliary Ducts.—B. B. Vincent Lyon presents this preliminary report based on a study conducted for fifteen months in France on men of the United States Navy Hospital No. 5, for six months in the Jefferson Hospital, and in his private practice. A total of over 1,000 observations were made on more than 100 cases. He states that they have proved and are in a position to demonstrate that Meltzer's assumption is correct, namely, that the instillation directly into the duodenum of magnesium sulphate, in solution of various strengths and in various amounts, is followed shortly afterward (within from two to fifteen minutes in most cases) by the evacuation of bile into the duodenum, which can be aspirated by the syringe or vacuum bottle. Magnesium sulphate seems to be a chemical messenger (hormone) which has the ability not only to relax the sphincter of the common bile duct and thereby drain the bile in the ducts, but also, simultaneously, to cause the gallbladder to be compressed and to empty its contents. The writer's observations have convinced him of the soundness of Meltzer's law of contrary innervation as applied to the gallbladder and biliary passages. Magnesium sulphate, however, is not the only chemical excitant which is capable of producing this action of the biliary apparatus. There are others capable of a similar action which will be reported later on. The procedure has shown that it is possible to segregate and study, cytologically not only bile from gallbladder, but also bile freshly secreted from liver itself. It has taught that one can differentiate with reasonable certainty between diseases of the various components of the biliary system, that is, between cholecystitis, cholelithiasis, and choledochitis in a more scientifically accurate manner than by any other method yet advanced. In

choledochitis, the bile first collected is definitely pathologic. It is more viscid, with an excess of flaky mucus, is usually turbid, and usually "off color;" cytologically, it contains pus cells enmeshed in mucus, epithelial cells, and occasionally red blood corpuscles; bacteriologically, cultures may show pathogenic organism. This type has been encountered in choledochitis and cholecystitis. In cholecystitis without choledochitis, the first bile collected is relatively normal, grossly and cytologically, and culturally does not contain pathogenic organisms But the second bile is grossly pathologic; it is more viscid than normal gallbladder bile; it is turbid with a flaky or stringy mucus; cytologically it will show inflammatory elements, and bacteriologically, cultures will show pathogenic organisms. In cholelithiasis there is evidence of cholecystitis, but in two instances it has been noted in addition that the bile contained a sediment that was gritty or sand-like in consistency. The writer has as yet seen no instances in which bile freshly secreted and collected from the hepatic ducts, after the gallbladder bile has been expressed, has given positive bacteriological or cytological findings suggestive of an infection involving or originating in the liver. It may be possible later to present differential proof of such a state.

11. Therapeutic Application of the Alteration of Brain Volume by the Intravenous Injection of Glucose.—Russell L. Haden refers to experiments reported by Weed and McKibben which show that the bulk of the brain can be controlled by a change in the concentration of certain elements in the blood stream. They have shown that the intravenous injection of hypertonic solutions of certain electrolytes and crystalloids causes a transient rise in the intraspinal pressure, followed by a marked fall which persists for a considerable length of time. On the other hand, the use of hypotonic solutions of the same substances causes a persistent rise in the intraspinal pressure. The injection of isotonic solutions causes no change in pressure. Since increased intracranial pressure is a very important factor in certain diseases, especially meningitis, the alteration of brain volume by intravenous injection of hypertonic glucose solution can be made use of to control the pressure. The intravenous injection of 25 per cent. glucose solution seems advisable as a routine measure in the treatment of meningitis. In two cases reported the direct cerebral action of the glucose seems demonstrated. Cases have also been observed which suggest that the intravenous injection of glucose may be beneficial in severe toxemias with cerebral depression in which a cerebral edema of varying degree is likely to develop.

5. The Relation of Graves' Disease to Diabetes and Glycosuria.—R. T. Williamson calls attention to a number of interesting facts which indicate the relation of Graves' disease to diabetes mellitus and glycosuria, and refers to cases met with in his practice which illustrate this relation from the clinical side. These are: 1. Graves' disease is occasionally followed by, or associated with, diabetes millitus, well marked or mild. 2. In Graves' disease frequently a temporary or intermittent slight glycosuria can be detected. 3. Mild diabetes is, in rare instances, followed by Graves' disease; such cases are extremely rare. In Graves' disease alimentary glycosuria is often produced much more readily than in health by the administration of a large quantity of sugar. 5. Both Graves' disease and diabetes mellitus occasionally develop directly after a sudden mental shock or after great mental anxiety of short or long duration. 6. Occasionally the family history shows that the two diseases have occurred in different members of the same family. Many other points of interest respecting the relation of the two diseases based on experimental work might be added. 7. In Graves' disease occasionally the patient suffers from nausea, sickness, and persistent vomiting and may be unable to take food and may very rapidly become wasted. In some of these cases there is a marked diacetic acid reaction in the urine, though the urine is free from sugar. The condition resembles the acetonemia of diabetic coma in many respects The relationship of these conditions should be taken into consideration in the treatment. If glycosuria is frequent or permanent than a diet chiefly of carbohydrate food is unsuitable in such cases of Graves' disease. In definite diabetes, associated with or followed by Graves' disease, of course the diet suitable for the form of diabetes detected should be advised, as the diabetes is usually more serious than the Graves' disease. To this statement there is one exception, and that is in cases of Graves' disease, complicated with persistent vomiting, with acetonuria, and with diacetic acid in the urine, if no glycosuria is detected sugar carbohydrates, such as tinned apricots, sweet fruit, etc., may be of much service for a short time, along with alkalies

10. The Iodides and the Thyroid.—Fred Hanson discusses the relation of the thyroid gland to iodine and the rôle of protein in the cell metabolism of the gland. He states that there is considerable probability that the active principle of the thyroid is a breakdown product of protein which may be, but is not necessarily, iodized. Iodine, if present, has apparently no direct effect upon the activity of the internal secretion, and yet there is no doubt that when that activity is diminished, it can often be restored to a certain extent by the administration of iodides. In discussing this apparent paradox he says that Jobling and Petersen have shown that unsaturated fatty acids have a powerful effect in inhibiting autolysis, but that in the presence of iodine these acids on becoming saturated lose their inhibitory effect, so that the ferments causing autolysis are free to act. The active principle of the thyroid is probably produced by the breakdown of protein in the gland, that is, by autolysis. This process would, according to Jobling and Petersen, be facilitated by the presence of iodine in the gland, because the inhibitory effect of fatty acids in the blood would be diminished or done away with owing to their saturation with iodine. Possibly the curative action of iodides in tertiary syphilis may be explained by the thyroid effect of the drug in thus favoring an increase in the active secretion passed into the blood, and so facilitating the absorption of lowly organized tissues such as gummata, etc. The same would apply to the use of iodides in enlarged lymphatic glands.

Acute Intestinal Obstruction and Danger from Morphine and Delay.—Murray Nathan Hadley states that he has reason to believe that the practice of giving repeated doses of morphine in grave abdominal crises is in no sense obsolete. He concedes that no one will deny the urgent need and absolute necessity of the first ¼ grain hypodermic of morphine and possibly the second in these cases. But before the second dose is administered the surgeon should be consulted and a definite surgical plan for the relief of the intestinal obstruction should be decided upon. Conservatism must be practised if the acutely obstructed cases are to be saved, that is the cases that have gone beyond the period in which operative procedures of any magnitude can be safely undertaken. There is only one thing that can be safely done and that is under local anesthesia, an enterostomy for relief of the obstruction, leaving the pathology to be attended to later. If a general anesthetic is given and a search should be made through a wide incision for the cause of the obstruction, and then an attempt made to resect, the patient will surely die. Experimentation has shown conclusively that the cause of death in acute intestinal obstruction is always the effect of toxins within the gut. The deduction from this is that toxic material must be eliminated from the gut above the point of obstruction. Several cases are cited which illustrate the dire consequences of delay in bowel obstruction, that delay still exists among the class of patients usually referred to the City Hospital, and that there is room for improvement in the surgical judgment in the handling of these cases.—*Indianapolis Medical Journal*, August, 1919

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK, FIRST DISTRICT BRANCH.

Thirteenth Annual Meeting, Held in Yonkers, October 15, 1919,

THE PRESIDENT, DR. JOSEPH B. HULETT OF MIDDLETOWN, IN THE CHAIR.

Presidential Address.—Dr. JOSEPH B. HULETT of Middletown said that as near as he could find out the most momentous subject before the medical man today was compulsory health insurance. The idea had gone out that the committee appointed by the Medical Society of the State of New York to study health insurance was biased. He did not think they were. They were trying to work out a plan to present to the House of Delegates when they should meet on November 22, which, if compulsory health insurance was adopted, would offer protection to the doctors. Unless the political atmosphere was cleared an attempt would be made to pass some sort of a compulsory health insurance plan at the next Legislature. The views he expressed on this subject were to be taken merely as personal ones. He happened to be in Germany when compulsory health insurance was started, and the doctors were not in favor of it. There were more reasons for adopting compulsory health insurance in Germany than in this country, because workmen were receiving small pay and were unable to pay their doctor bills. Then again the State wanted to run everything. He had been told that there was more malingering in Germany since compulsory health insurance went into effect than before. Furthermore, there was no stimulus to the men to be good workmen, because if they got up a little in the scale they had to pay thei own doctor bills. Dr. Hulett said he also happened to be in England when they took up the subject of compulsory health insurance there and passed the law establishing it. The doctors there were also very much against it, and it had not been a success. The matter was too big for the State to handle so it was farmed out to insurance companies. It had proved so unsatisfactory to the doctors that it had interfered with the study of medicine and when the war broke out England found herself short of doctors. Personally he felt that the plan was un-American. He did not think we should adopt foreign failures. He thought that in America every man wanted to feel that he could select his own doctor and the doctor wanted to feel that he could select his patients. He had canvassed his own county in regard to the subject and found the people did not want it. It was unnecessary because they had a system of town physicians under which no one was neglected. Another point against compulsory health insurance was the expense of its administration. It was said that it would cost from fifteen to twenty-five million dollars a year, and it did not seem that we should adopt a plan that was going to cost the people millions of dollars and one that no one could say where it would end. It was unjust to the taxpayer, to the employer, and to the workingman; a man with a small family would have to pay as much as the man with a large family. It was also unjust to the doctors and druggists. The doctors had educated themselves without the help of the State and they felt that they should be left to work out their lives in their own way. It seemed further that it would lead to inefficiency on the part of the doctor, for to get an appointment he would have to be something of a politician and this might lead to his spending at least a part of his time learning something about politics. The druggists said that they had studied pharmacy and put their money in their business just like any other merchant, and they felt that they should be allowed to go on like any other storekeeper. It was said that the administration of the scheme would require 25,000 political managers. It would cost a great deal to get out the printed reports that would be required and a great deal to mail them. If a doctor had to report every disease and turn the report over to a politician he did not see how he was to keep his oath of secrecy. Under the Workmen's Compensation scheme he had been asked to divulge secrets and he had refused to answer such questions. He had told them that he had taken the oath of secrecy when he received his license to practice medicine and he intended to keep it. A few labor leaders wanted compulsory health insurance, but the rank and file did not want it. Some doctors wanted it; some of these were high in the profession and would not be affected by a compulsory health insurance law, and some doctors who were not making very much; but the rank and file did not want it.

Address. Dr. GRANT C. MADILL of Ogdensburg, President of the Medical Society of the State of New York, said, in part, that there had never been a time in the history of medicine when there were so many new and perplexing problems that had to be met, but that men of the medical profession should remember that they were not alone in this respect, for the whole world was in a condition of unrest and discontent, and there were many problems to be solved outside of medicine. They must remember that they were citizens as well as physicians. They must take a very broad view of the whole situation. The State had some very serious problems to meet. One of the first of these was the Medical Practice Act. A bill had been introduced into the Legislature last year known as the Medical Practice Act or the Registration bill. It required the annual registration of all doctors and the payment of an annual registration fee of two dollars. Many doctors expressed themselves as opposed to paying a tax of two dollars a year to protect the public, since, as a profession, they had always been working to protect the public. Veterinarians and dentists had been registered according to this plan and had found it very satisfactory. Many doctors, however, felt that the State should protect the public and the medical profession against the illegal practitioner. He believed this bill should become a law. The bill was backed by the State Board of Education and by the medical profession, but the chiropractors had prevented its passage. The bill would furnish a means of finding out those who were practising medicine illegally and then they could be prosecuted. New York City had a way of protecting itself against the illegal practitioner through the activities of its County Medical Society, but throughout the State there were many illegal practitioners who could not be reached under present conditions. Another matter of special importance to the medical profession was that of diagnostic clinics. This was perhaps considerable of a problem to solve, but it could be done and he believed it would be solved. The person of means had no difficulty on getting the advice and consultation of specialists and experts, but there was a large class of people unable to get such expert advice. It would be easy to organize these diagnostic clinics in the cities. In the smaller communities he thought it could be worked out, as there were few cities or even smaller towns that did not have a number of specialists. If such men were lacking in a community it might be arranged so that an expert from a neighboring city might come to the smaller community for a day or two a week. This might savor somewhat of State medicine, and though he was opposed to State medicine it did not take a great deal of foresight to see that State medicine might come. In connection with the diagnostic clinic there should be some plan by which the patient was returned to the doctor from whom he came, and in this way the specialist would not be exploited at the expense of the general practitioner. Another matter was that of physicians locating in rural communities. The older practitioners who located in small communities and in hamlets were fast disappearing and the young men were not taking their places. The young men, if asked to locate in a rural community, said they could not afford it, as it cost so much to be educated and they could not live on the fees they received in a rural community. Some communities had even offered a certain sum if a young man would locate there. The difficulty of getting physicians to locate in small communities might be overcome by the automobile, the motor ambulance, and the construction of hospitals in smaller towns. This would make up for the loss of the family physician. The hospitals now in existence could not keep up to the demands made upon them, and if the young physician would not go into a rural district the State would have to provide for the people. This was a problem upon which the State Society could not act, but it was a very serious problem today. Dr Madill next discussed the resolution introduced before the House of Delegates of the Medical Society of the State of New York at its last session, providing for the establishment of a Bureau of Legislative Information with headquarters in Albany. This resolution, together with the report of the Committee on Health Insurance, would be discussed by the House of Delegates at its meeting on November 22. He had spoken of this so that those present could instruct their representatives on the matter so that their wishes might be expressed. The subject of compulsory health insurance which was to come up at that time was exciting more interest in

the medical profession than any question since the revision of the code of ethics thirty years ago. Dr. Madill read the resolutions passed by the House of Delegates providing for the appointment of a committee to investigate the subject of compulsory health insurance and urging action before a law was passed which would be greatly to the detriment of every one concerned. When the House of Delegates met in November, if there was a minority report and the House adopted it, that ought to settle the question entirely. If the House decided to accept a compromise which they believed would be best for the community and best for the profession, that action the profession ought to accept. If the House of Delegates decided to fight the thing to the finish and go down with flag flying, we ought to stand by that. Many thought that the moment one began to study, discuss, or think about compulsory health insurance he was immediately a traitor to the profession. We ought to know both sides of the subject. There were throughout the State many organizations against compulsory health insurance. Just how far the medical profession should get into politics was to his mind a question. The medical profession had at present the entire respect of the community. He felt that on the whole it had been pretty well taken care of by the Legislature. The medical profession had always stood for what was best for the public and best for the profession. If they got into politics it might act as a boomerang; they might get into a position where they could not get from the Legislature what was best for the public and best for the profession. It was time to stop, and consider, and look ahead. He believed the Medical Society of the State of New York, which was incorporated 113 years ago and since that time had always stood for the highest ideals in the practice of medicine and had always had in mind first the public, was in a position to take vigorous action and to carry out the wishes of the public in a dignified and honorable manner.

Health Conservation League.—Dr. ALBERT T. LYTLE of Buffalo described the organization and objects of the Health Conservation League which was organized June 4, 1919, and incorporated under the Laws of the State of New York, June 19, 1919. He stated that the objects of the Health Conservation League were to bring into relations of mutual helpfulness and understanding the various organizations of physicians, dentists, nurses, and pharmacists throughout the State of New York; to make combined action possible when deemed expedient; to promote and protect public and individual health and to enlighten and influence public opinion in all matters affecting the health of the people; to collect, arrange, and tabulate facts, opinions, and writings bearing on social, economic, and legislative questions affecting the health welfare of the public and the members of the League; to convey frequently and promptly by bulletins or otherwise to each individual affiliated with the League early advices on all civic movements that challenged the interests of the League so that the members might be correctly informed. The Constitution and By-laws of the organization were modelled on those of the Medical Society of the State of New York. Members of societies or other organizations of physicians, dentists, nurses, and pharmacists who were duly licensed to practise their respective professions in the State of New York were eligible for membership, and were known as active members. Members of these professions who were duly licensed in their several professions but were not members of organizations above mentioned were known as associate members. The dues were not more than $1 a year at present. Among the immediate problems with which the organization was concerned were: (1) The establishment of a Bureau of Information to accumulate facts and knowledge of matters and movements affecting the health welfare of the people, and especially the four professions, particularly as to legislative, economic, social, sanitary, and other movements, whether State, national, or international. (2) The preparation and pronouncement of ethical principles to govern the interprofessional relations of the four professions of the League with the public. (3) The rapid establishment of the League as an advisor to legislators upon all bills introduced into the Legislature affecting the health welfare of the people and as a source of reliable information upon all related subjects. (4) The quick demonstration to the public of the reliability and value of the information and advice presented to it by the League on all subjects affecting health welfare. (5) The promotion and stimulation of active cooperation with other existing civic organizations. (6) The study and consideration of the attitude of the four professions toward the establishment of State compulsory health insurance. (7) The modification of the narcotic laws so that they should accomplish the purpose for which they were intended, while at the same time making it possible for the members of the League to comply easily with their provisions. The organization was opposed to any of the schemes of compulsory health insurance thus far promulgated.

Dr. JOHN P. DAVIN of New York recalled that several years ago the Medical Society of the County of New York had taken a decided stand in opposition to compulsory health insurance from which it had never since deviated. One grave question in connection with compulsory health insurance was the interjection of politics. This phase of the question had been thoroughly studied by Mr. Jerome K. Lynch, Chairman of the State Industrial Commission, and he had very emphatically stated that the question of compulsory health insurance was not one of politics, but one of social welfare. At present the propaganda for health insurance was propaganda for political power, influence, and prestige. At the last meeting of the House of Delegates of the Medical Society of the State of New York the delegates to the American Medical Association were instructed to work against compulsory health insurance, and their activities were limited to the presentation of those instructions. They did nothing else. Four times bills providing for compulsory health insurance had been before the Legislature and had been defeated, but the question was coming up again because influential men in the medical profession were keeping it alive.

School Health Service in New York State.—Dr. FRANK W. BARROWS of Buffalo, of the New York State Department of Education, spoke for Dr. William A. Howe and gave a lantern slide exhibit. He said we had heard much lately of the importance of the care of the national health. It was found that the school stood at the entrance of the work of building up a strong nation both physically and mentally. Many questions were asked at the Department of Education as to what it was aiming at in the enforcement of medical school inspection. This he said could best be illustrated by showing the forms that were used largely throughout the schools in keeping records of the physical condition of the school children. Not all of these blank forms were used in all the schools of the State but they were distributed as samples, and some of them were quite generally used. The Medical Inspection Law was passed about six years ago and provided for medical inspection of all school children outside of large cities of the first class which already provided for the medical inspection of school children under their municipal laws. Something like 75 per cent. of all school children were receiving physical examinations in the public schools. Some 30 per cent. of those found handicapped were treated for remediable conditions. That was only a beginning and the question was how to provide treatment for a larger proportion. Very strong emphasis was to be laid on the fact that in doing this work there was no intention to interfere with the prerogatives of the family physician. Fewer children, however, came each year with certificates from the family physician and more and more preferred to rely upon the examination provided by the schools. The great need was for more work in the pre-school age so that children would be in good condition with remediable defects corrected when they entered school. Attention was called to the interdependence of physical and mental conditions. The Board of Education had succeeded in getting specialists to care for children who were unable to pay for such attention and had made arrangements whereby hospital care could be provided for children at very much less than the usual rates, provided the children came recommended by the school doctor. There was no child in any part of the State, however remote, who could not receive relief from a physical defect. A great deal of volunteer dental work was also being done. The Department of Education did not recommend that children be examined at so much per capita, a certain number to be examined in a given period. This inspection should be a thorough physical examination. The value of the school nurse was not only on account of the work she did in following up the child and seeing that his defect was corrected, but because of the knowledge she carried to the family. If she sometimes seemed to overstep her prerogatives and to prescribe it was often because medical advice was not available. If the children were examined for physical defects, why not examine all teachers, since the teacher with tuberculosis was a menace in the school room? Why not go a step further and examine

the janitors who were often capable of doing more harm than a teacher suffering from tuberculosis?

Dr. SAMUEL E. GETTY of Yonkers said that as he had watched these slides showing the blanks he had been struck by the thought that the State Department of Education was working from rather an idealistic standpoint. He thought they were asking too much when they asked the doctors in the rural communities to do this work for nothing. The Department was paying every one else for his or her services but was asking the poor country doctor to furnish free clinics for the children. If the work was worth while, and it was, then it was worth paying for. He did not see why the doctors should be asked to do this work for nothing. He also resented the statement that had been made during the talk that children had defects when they came to school owing to the doctor's neglect. The doctor could not treat children unless they were brought to him. Nine out of ten times it was not the doctor's fault that these defects had been allowed to run along without attention

Dr. S. W. S. TOMS of Nyack asked how some of these examinations were carried out. On one of the cards it said the child was to be referred to the family physician, dentist, oculist, optometrist, etc. In one community he knew of the children's eyes were being cared for by an optometrist. He hoped the State Board of Education did not stand for that sort of thing, because the care of a child's eyes during the growing age was very important. Frequently children had perfectly good vision but complained of their eyes after prolonged use. They could see a blackboard perfectly well. Some of these children had slight defects that could not be properly corrected without the use of a mydriatic. The mydriatic could be used on Saturday and by Monday the child could go to school and use his eyes as usual. Again, these children who were deficient in vision did not always require glasses. Dr. Toms stated that he knew of one instance where the principal of the school had a wife who was an optometrist and he was sending the pupils whose eyes needed attention to her. He wished Dr. Barrows had told them more about the school nurse for he thought the nurse was the most important part of the work, as she could go and advise the family to have defects corrected when a doctor could not do so because he might be suspected of having ulterior motives

Dr. E. W. WEBER of White Plains said he only wished to emphasize what Dr. Toms had said in respect to the importance of the follow-up work done by the nurse. This part of the work could not be over-emphasized because a child with a defect might repeatedly be left back in his grade because of that defect, so that its correction was a most important matter and the nurse was doing a splendid service when she saw that these defects were cared for. With reference to compulsory health insurance, if more time were devoted to preventive work during the preschool age and in the schools there would be little need for health insurance.

Dr. BARROWS, in closing, said that with reference to the voluntary service given by the doctors in carrying out the medical school inspection law, he agreed thoroughly with what was said, but when the trustees refused to hire medical inspectors or, in remote districts where there were no inspectors residing in the district, this seemed to be the only course open to them for the present, but they hoped in time to have medical inspectors and school nurses in all districts. The present state of affairs was only temporary. As to physicians being responsible for the defects of children when they entered school, the speaker had practised medicine himself and was willing to take his share of the responsibility. The thing to be done was to change the entire attitude toward this matter. Why should the physician not know from time to time what should be done in the case of children in his practice? The fact was the physician was called upon only in case of emergency and he did not constantly look after the child's health. He did not have the opportunity. What he would like was to see the relation of patient to physician revised, so the physician would be the pastor and director of the child's health just as the clergyman was the pastor and director of the family in religious matters. In reference to taking children to the optometrist: The wording of those certificates had been changed by eliminating the names of the various specialists, so that the word optometrist no longer appeared. The difficulty was not with the Board of Education but with the law. Under the law the optometrist had the same right as the oculist. The certificates now read "kindly take the child to the family physician who will advise you in regard to the treatment needed and where it may be obtained." That should be satisfactory to the physician. As to the school nurse, if there had been more time he would have liked to say more about her work. If she appeared at times to be practising medicine she was deserving of mercy. She was doing the best she could to bring about the time when the physician would come into his own. The physician should remember that there were others in his community who were just as vitally interested in maintaining the integrity of his practice as he was himself and by aiding them he was aiding his own profession.

Book Reviews.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE PREVENTION OF DENTAL CARIES AND ORAL SEPSIS. By H. P. PICKERILL, M.D. 374 pages with 74 illustration. Published by Paul B. Hoeber, New York.

EXPERIMENTAL PHARMACOLOGY. By HUGH MCGUIGAN, Ph.D., M.D. 245 pages with 63 illustrations. Published by Lea & Febiger, Philadelphia.

PHYSICAL DIAGNOSIS. By RICHARD C. CABOT, M.D. 527 pages, 269 illustrations. Published by William Wood & Company, New York.

OXFORD MEDICINE, ADVANCE PAGES. Edited by HENRY A. CHRISTIAN & SIR JAMES MACKENZIE. 149 Pages. Published by The Oxford University Press, New York.

MEDIZINISCHE TERMINOLOGIE. By WALTER GUTTMANN. 1307 pages. Published by Urban & Schwartzenberg, Berlin.

THOUGHTS OF A PSYCHIATRIST ON THE WAR AND AFTER. By WILLIAM A. WHITE, M.D. 137 pages. Published by Paul B. Hoeber, New York.

GRUNDRISS DER PHYSIOLOGIE. By Prof. Dr. C. OPPENHEIMER. 461 pages. Published by George Thieme, Leipzig, Germany.

VICIOUS CIRCLES IN DISEASE. By JAMIESON B. HURRY, A.M., M.D. 377 pages, Illustrated. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

TREBALLS DE LA SOCIETAT DE BIOLOGIA. Edited by A. PI SUNER. 352 Pages. Published by the Institute d'Estudis Catalans, Barcelona, Spain.

THE SURGICAL CLINICS OF CHICAGO. August, 1919. 1056 pages, with 117 illustrations. Published by A. B. Saunders Company, Philadelphia.

PLASTIC SURGERY, ITS PRINCIPLES AND PRACTICE. By JOHN STAIGE DAVIS, M.D. 770 pages, with 864 illustrations. Published by P. Blakiston's Son & Co., Philadelphia.

KOMPENDIUM DER TOPISCHEN GEHIRN UND RUCKENMARKSDIAGNOSTIK. By ROBERT BING. 235 pages, with 97 illustrations. Published by Urban & Schwarzenberg, Berlin and Vienna.

SEVENTEENTH ANNUAL REPORT OF THE DIRECTOR OF THE BUREAU OF SCIENCE. By ALVIN J. COX, Dir. 79 pages. Published by Manila Bureau of Printing, Manila, P. I.

QUARTERLY MEDICAL CLINICS. A series of Consecutive Clinical Demonstrations and Lectures. Edited by FRANK SMITHIES, M.D. 408 pages. Publishd by Medicine & Surgery Publishing Company, St Louis.

THE TREATMENT OF GOUT. By J. B. BERKART, M.D. 21 pages. Published by Oxford University Press, American Branch, New York.

ERRORS OF ACCOMMODATION AND REFRACTION OF THE EYE. By ERNEST CLARKE, M.D. 244 pages. Published by William Wood & Company, New York.

DISEASES OF INFANTS AND CHILDREN. By H. D. CHAPIN, A.M., M.D., and G. R. PISEK, M.D. 592 pages, with 145 illustrations. Published by William Wood & Co., New York.

THE MEDICAL RECORD VISITING LIST OR PHYSICIANS' DIARY. Published by William Wood & Co., New York.

ATLAS OF OPERATIVE GYNAECOLOGY. By BARTON COOKE, HIRST, M.D. 292 pages, with 164 plates and 46 figures. Published by J. B. Lippincott Company, Philadelphia.

THE FUTURE OF MEDICINE. By Sir JAMES MACKENZIE, M.D. 238 pages. Published by Oxford University Press, New York.

INFLUENZA, WITH ESPECIAL REFERENCE TO THE PANDEMIC OF 1918.

BY J. R. HURLEY,

PASSED ASSISTANT SURGEON, U.S.P.H.S.

IN dealing with this subject the writer is not expecting to present any new theory or discovery of his own regarding influenza. It is hoped, however, that by reviewing the literature available on the subject to take stock of what is known about it; to sift out the various modern findings and theories advanced by physicians and others who have had adequate experience during the 1918 pandemic, that it may be apparent how little as well as how much is actually known about this disease. It would seem that opinions in the profession are rather in a state of flux regarding particularly the etiology and the best mode of treatment of the disease.

It was the desire of the writer to bring forward if possible something definite or established concerning the etiology, and something useful regarding the mode of spread, and the means of prevention and treatment of the disease. It appears that he will somewhat fall short in this, principally because in so far as ascertainable there has been no theory nor discovery on these subjects of preeminent value, or which has received the unanimous acceptance of the medical profession either here or abroad.

The various facts and expressions of belief will be set down, however, which it is hoped will not be without interest, and such conclusions may be drawn as seem warranted.

Historical.—Under various names large epidemics corresponding to epidemic influenza have occurred at irregular intervals since accurate descriptions have been made of disease. It is likely that at still earlier periods this disease was confused and combined with other epidemic disorders and so did not stand out as an entity. An editorial in the *Journal of the American Medical Association* contains an interesting account of the past history of influenza as follows:

In early English literature this disease is spoken of under a variety of terms. Creighton recognizes it under the name of "ague," used by the British seventeenth century authors. In 1658 Cromwell is said to have died from this disease, when Morton says the country was one vast hospital. The Italian term "influenza" first came to England in association with the epidemic of 1743, and it has been employed in connection with the great epidemics of 1833, 1847, and 1888-90. About 1712 the French term "La Grippe" came into use and has been periodically revived ever since. The great pandemics usually originated in the Far East and gradually extended westward. The rate of human intercourse between various parts of the world determined the rapidity of the extension. Influenza has embraced America in several pandemics. In his remarkable work on epidemic diseases, published in Hartford in 1799, Noah Webster locates the first American epidemic, of which he could find an account, in 1647. It passed through the whole country and extended to the West Indies. There were between 5,000 and 6,000 deaths in Barbados and St. Kitts. In 1655 a second severe epidemic occurred in America. Benjamin Rush describes an epidemic in 1789 in Philadelphia which was brought there by members of the First Congress, which had assembled in New York, and Daniel Drake records a widespread epidemic in the West in 1807.

The last preceding pandemic of 1889-90 is said to have originated in the Orient in the spring of 1889. It reached Moscow in September of that year, and Petrograd in October. By November it had appeared in Berlin, and London suffered a month later. In the latter part of December it reached New York. Within a year the disease had visited nearly every part of the world.

The recent pandemic seems to have spread even more rapidly than its predecessor, due, perhaps, to the more speedy transit conveyances now available for human travel. Within nine months of its first appearance in Western Europe it has spread throughout the civilized globe. Having been noted in France and Spain in the spring of 1918, by Christmas of that year it had appeared in places as far remote as Bombay, where it caused 15,000 deaths, and in Argentine, and Cape Town, South Africa, in which latter place according to the newspapers there were at one time hardly enough well people alive in the city to bury the appalling number of dead, and 2,000 children were left destitute as a result of the disease. En route to South America it visited Havana, Cuba, and other parts of the West Indies, where it was reported to have raged with an unabated virulence. In far off Samoa the disease had affected 80 per cent. of the natives and it became necessary for Australia to send a relief ship to their aid.

It seems probable that not since the Black Death of the time of Daniel Defoe has such a plague swept over the world. In India alone 3,000,000 deaths have occurred attributable to the influenza. Delhi with a population of some 200,000 had 800 deaths a day. A British writer estimates that throughout the whole world this pandemic of influenza has sent into eternity over 6,000,000 souls.

The recent pandemic in the United States has commonly been termed the Spanish influenza, though nothing has been found in the literature to show that epidemic influenza originated in Spain either recently or in past visitations. In fact its

occurrence elsewhere in Europe in 1918 had been noted before its appearance in Spain.

The ultimate source of the 1918 pandemic is not clear. No satisfactory connected account regarding the origin and march of this last epidemic thus far has been found. The war censorship is probably the reason.

It would seem that it began in Western Europe in the form of a mild disease like the usual winter grippe experienced sporadically throughout the United States for a number of years. It gradually assumed increased virulence in Europe till a degree was reached corresponding to the strain prevalent in this country during the Fall of 1918. This increase of virulence is easily explainable along the lines commonly observed by bacteriologists in strains of organisms, the pneumococcus for instance, which markedly increases in virulence when passed rapidly through a succession of susceptible animals, such as the rabbit. It might be of interest to note that a German author early suggested that the virus may have been brought into Europe from the Orient in the persons of Chinese coolies imported as laborers behind the Allied battle lines. This is not an unreasonable hypothesis as we have been long accustomed to look upon China with its teeming millions living under the most unhygienic surroundings as the hot bed of all the infections which affect the human race; and various pestilences in the past have been directly traced to that source. However that may be, influenza was first reported as being prevalent among the Allied troops in France during the latter part of March, 1918, and almost at the same time numerous cases appeared among the adjacent civil population. About 25 per cent of all who were exposed were attacked. The death rate, however, was low.

It is reported that the first cases in Germany appeared among the soldiers who had fought with presumably infected American troops during July.

A disease which was widespread among the American Expeditionary Forces in France during April, May, and June of 1918, was characterized as "Three Day Fever." Its effects were so comparatively mild then that it was hardly thought to be influenza; though there is but little doubt that it was the beginning of the great influenza epidemic which in later months took on increased virulence.

Regarding influenza in the British Expeditionary forces, the influenza committee of the Advisory Board to the Director General, Medical Service, France,[1] reports that the disease assumed epidemic proportions in the first and second armies in France in April, 1918, and continued throughout the month of May. It appeared nearly simultaneously in Rouen and Wimereux, in April. According to this report, the disease appeared very contagious, and spread rapidly, affecting a high percentage of those exposed. In the second army a brigade of artillery had one-third of its whole strength taken ill within 48 hours, and in the brigade ammunition train only 15 men were available for duty out of a strength of 145.

Influenza was reported present in epidemic form in Taranto, Italy, and aboard the ships of the Navy in that locality as early as the middle of May.

The epidemic of influenza was said to have begun in Spain about May 25, 1918, first appearing in Madrid. A Spanish author (Carlan[2]), concerning the outbreak, remarks: "The only strange thing up to the present time is that the epidemic has appeared in Madrid without etiological antecedents connected with similar epidemics in other populations." It would seem that due to the rigid censorship then obtaining it was not generally known in Spain at that time that the Allied armies had been suffering from the disease for a month or two preceding its development in Madrid. It is interesting to note that in Spain the disease had been given the name "trancazo," meaning literally "a blow with a bar," expressive of the sudden sensation of depression and fatigue felt by the person afflicted with the disease.

Strange to relate, influenza appeared in epidemic form during the month of June, 1918, in Manila, P. I. Contant[3] is the authority for this statement. Similarly to the Spanish author above quoted, he speculates as to its origin. Evidently, through the censorship rules, its prevalence in western Europe was hidden from him, as it was from us in America and elsewhere. He wonders if the event in Manila was to be the forerunner of a world-wide epidemic such as had occurred in 1889-90. Three hundred cases came under his observation in a Manila hospital in which there was a mortality of 2 per cent. The virulence of the strain and the symptoms were quite similar to those observed during the epidemic which ravaged America four months later, the hemorrhagic manifestations being especially remarked upon.

Influenza continued to prevail and spread throughout Europe, with ever-increasing virulence during the summer of 1918. Hewlett and Alberty[4] report cases of the disease as first appearing in U. S. Navy Base Hospital No. 2, France, on July 16, when 19 Hindoos removed from a single vessel, ill with influenza, were admitted to that hospital.

According to the *British Medical Journal*[5] the epidemic among the civil population in England reached its maximum in July, and it is estimated that between June 15 and August 3 it caused between 1600 and 1700 deaths in London. It is also there learned that during this period the disease was prevalent in Italy, and likewise occurred in virulent form in Switzerland. This journal goes on to remark: "The recrudescence of the epidemic in London, which occurred during October, is quite in accord with previous experiences of the behavior of the disease at the onset of cold weather."

The first that was seen of this highly virulent strain of influenza in the United States was among the crews of ships arriving from abroad during July and August, 1918. Several accounts of epidemics on shipboard were published in the newspapers regarding certain ships arriving at New York, Newport News, and other ports. There is nothing to show, however, that the epidemics that developed in these cities in late September and October were directly traceable to these infected ships. According to all accounts, the disease first made its appearance in America at the port of Boston, next appearing at Camp Devens, a short distance away. From that center it rapidly spread, fanlike, in all directions. Keegan[6] of the U. S. Navy Medical Corps states that the disease was first recognized at the Naval Hospital, Chelsea, Mass., August 28, 1918, the first

patients coming from the receiving ship at the Commonwealth Pier, Boston. He did not trace the source of the infection in these cases, but expresses the belief that the infection came from Europe. In his opinion, then expressed, the disease was the result of a strain of Pfeiffer bacillus rendered unusually virulent by rapid passage through so many susceptible men easily accessible in the military camps and trenches in Europe.

The *Boston Medical and Surgical Journal*,[7] in its issue of September 19, 1918, carried a warning to the profession and the public that influenza was prevalent among the sailors on Commonwealth Pier, and conveyed the information that the State Board of Health desired to warn civilians to take such measures as they could to protect themselves from the expected spread of the disease, as more than 350 cases had been officially reported from the pier during the preceding week. The Health Board was quoted as saying: "With a focus of infection of this size it seems probable that the disease will escape into the civil community in spite of all efforts at control." The warning was in vain in so far as any practical results that accrued, but it was timely and sagacious, as the expected spread occurred just as predicted.

One of the next places reporting a virulent epidemic of influenza was the Great Lakes Naval Training Station, where it appeared about the 9th of September. This station is located about 30 miles north of Chicago. It has nowhere been stated that this outbreak was traced to the one on Commonwealth Pier; but from the frequent exchange of recruits and officers between the various naval bases during the war, it seems likely that the infection was conveyed from Boston to Great Lakes in this manner, especially as the infection did not manifest itself through an increased civilian death rate in the city of Chicago till the last week in September.

On August 16, 1918, the Surgeon General of the Public Health Service issued to medical officers in charge of United States quarantine stations a circular instructing them to be on the alert to detect cases of so-called Spanish influenza aboard ships arriving from abroad, on account of the prevalence of the disease in Europe. This to the end that the proper local and State health authorities might be notified in accordance with the U. S. Quarantine Regulations, so that the necessary cooperation might be extended in an effort to stamp out the disease.

On September 28 the Public Health Service caused to be printed in *Public Health Reports*, and reprinted for wide distribution, a short article in popular style, under the caption "Spanish Influenza; Three-day Fever; the Flu," with the idea of acquainting the public with the nature of the disease and what could be done through personal prophylaxis to guard against incurring the infection. About the same date the service caused to be similarly published and reprinted for distribution, principally to physicians, a brief monograph bearing the title "Epidemic Influenza," which gave an outline of the history, symptoms, diagnosis, prophylaxis, and treatment of the disease.

On the recommendation of the Surgeon General, both the House and Senate, in early October, passed joint resolution No. 333 appropriating $1,000,000 to be expended by the Public Health Service for combating the epidemic. This fund was extensively used for salaries and expenses of physicians appointed temporary acting assistant surgeons, who were recruited in the larger cities and sent out into the more remote sections where the epidemic was raging, to render medical assistance to sufferers from the disease. There were numerous smaller towns and rural districts, where, through causes arising out of the war, the doctors had gone away, and people were dying from the malady without medical care, no physicians being accessible even to sign death certificates.

From the middle of September on the disease marched from the Northeast to the West and South, throughout the United States about as rapidly as man travels on the train. By September 28 it had appeared in epidemic form in Maine and New York City, and by October 5 it was raging in Illinois, Maryland, Virginia, North and South Carolina, and Pennsylvania, and in Philadelphia had assumed an extraordinary virulence. By October 12 the epidemic had developed in Ohio, Indiana, Kansas, and Alabama, and had got as far south as Louisiana and as far west as Southern California and Seattle, Washington. By this time, also, it was beginning in West Virginia, Georgia, Arizona, New Mexico, and Florida.

By October 19 it had spread into practically every State in the Union, as according to a tabulation printed in *Public Health Reports* all States which had not previously reported cases by the end of that week reported an unusually high morbidity from the disease, with increasing death rate. On an average, the various localities reported the peak of the epidemic about three weeks after it became prevalent, and by about six weeks from the time it began the epidemic, as such, was practically over. It thus spread wavelike from the North and East to the South and West, and was declining in Massachusetts, for instance, when it was at its height in New York City, and just beginning in the Western States. By November 9 the epidemic was on the wane in all States save those in the extreme South and West, and by November 30 the pandemic was practically over everywhere in North America save for flareups here and there in certain communities. Its beginning, spread, and decline were quite analogous to the progress of former prairie fires in the great Middle Western plains.

The source and means of introduction of the infection into the State of Washington is known, and worth recounting here.

In an article by Ely, Lloyd, Hitchcock, and Nickson [8] it is said that influenza first appeared in the Puget Sound Navy Yard, Bremerton, near Seattle, on September 17, 1918, and that it was introduced by a draft of 987 sailors received from Philadelphia, a number of whom arrived ill, or came down within a few hours after reaching their destination. As a result, Seattle and the State of Washington were infected somewhat ahead of the other West Coast States. According to the record, influenza did not assume epidemic proportions in the State of Oregon for nearly a month after this Bremerton Navy Yard epidemic.

The Judge Advocate General of the army ordered the transfer of drafted men into military camps

discontinued after the epidemic had got well under way, but too late, it seems, to halt its spread in any perceptible degree, though, of course, the order served to diminish the influx of new cases into the camps.

While with the beginning of 1919 the great pandemic, as such, may be said to have ended, it is likely that the disease will continue to manifest itself in individual cases and local flareups for the next year or two, at least, if the past histroy of influenza is any criterion.

Incidence.—It has been stated that influenza is more deadly than war. There is no question as to the truth of the statement as touching the relative effects of the epidemic and the war upon the United States.

The Bureau of Census at Washington reports that for 46 large cities in the United States, with a total population of 23,000,000, statistics show that from September 8 to November 9 inclusive 82,360 deaths occurred from influenza and pneumonia. The normal deaths in these cities for the same period would be 4,000, leaving approximately 78,000 deaths attributable to the epidemic.

The total loss of life from all causes in the American Expeditionary Forces, as officially furnished by the chief of staff, up to November 26, 1918, amounted to 22,768. From this it appears that the deaths from influenza alone occurring in the 46 cities with a population of about one-fifth of that of the United States exceeded by a considerable margin the casualties from all causes of the American Army of approximately two million men in France.

The Public Health Service was quoted in the newspapers as estimating on December 4, 1918, that approximately 350,000 deaths occurred from influenza and influenza pneumonia among the civil population of the United States from September 15 to November 30, 1918.

Influenza not being a reportable disease in most States before the epidemic, and for other obvious reasons, the actual number of cases that occurred in the United States will never accurately be known.

An official summary made public by the War Department on December 10, 1918, showed that there were 338,257 cases of influenza up to December 1, with approximately 17,000 deaths, in the U. S. Army camps and cantonments.

From a bulletin of the Bureau of Medicine and Surgery of the Navy[9] it is learned that from the inception of the epidemic up to and including November 30, 1918, the records show 69,325 admissions for influenza for the entire Navy, ashore and afloat, with 3,812 deaths from the disease. On the basis of a complement of 614,000, it is found that this represents a death rate for the epidemic of 6.3 per thousand, the percentage of personnel attacked being 11.11, and the case fatality rate 5.44 per cent. of those attacked.

Regarding the Fourth Naval District, Pickerell[10] reports that out of 15,000 men, 3,305, or 22 per cent., incurred influenza. Of those attacked, 15 per cent. died. The average mortality for the whole number of cases was 5 per cent.

This tallies fairly well with the average percentages of the various conditions for the whole country. Of all the cities in the United States, Philadelphia showed the highest death rate during the epidemic period, with 7.4 per thousand sick and well. Pittsburgh came next with 6.8 per thousand, and Baltimore was third with 6.5 per thousand. The influenza death rate in Boston was 5.5, while in Washington, D. C., it was 5 per thousand. In Philadelphia there were 8,080 deaths reported from influenza and 5,295 from pneumonia. In Baltimore during the epidemic 1,624 persons died from influenza and 2,388 from pneumonia. Pittsburgh had 1,989 deaths from influenza and 2,410 from pneumonia. In Boston there were 3,689 deaths from influenza and 1,099 from pneumonia.

Etiology.—Regarding age, all authorities are agreed that the recent epidemic has attacked and killed preponderantly those between the ages of 20 and 40. Youth and old age have not been spared, but by far the greatest incidence and mortality have occurred between the above-mentioned ages.

As to sex, the males have been more largely attacked, though females have by no means escaped. There is nothing to show that females are less susceptible. Of the sex, pregnant women have suffered disproportionately, the mortality among them being especially high. In all probability, the reasons for males being more largely attacked are that they were more exposed through their activities, also large numbers of men were congregated in military camps where all the conditions were favorable for rapid spread. Fatigue, no doubt, played a part in increasing their susceptibility.

Regarding race and social condition, no statistics are thus far available, but upon general principles it is doubtful if these factors exercise any effect.

Personal condition is undoubtedly ofttimes a determining factor. Certainly a large percentage of those exposed do escape in the beginning of the epidemic, though they may come down at a later date. As in other respiratory diseases, alcoholism is a contributing factor. In brief, it may be said that anything which lowers vitality predisposes by that much to the disease.

The weather is often spoken of as influencing the virulence or prevalence of influenza at certain times and places. It is more than doubtful if the weather has anything to do with it. Inclement weather, by driving people indoors, where they herd more closely together, of course by that much and in that manner favors the spread of the disease. The laity are prone to attribute an occult influence of the weather upon the epidemic. Hitherto we have been accustomed to look upon the influenza as being a cold-season disease. The recent pandemic prevailed in various places and spread uninterruptedly through all kinds of weather: Spring and summer in Europe; late summer, autumn, and early winter in the United States. During the three months in which influenza raged in the United States the weather in the different sections varied nearly as much as the locality: the cold, wet weather of fall in the North Atlantic States, the cold, dry weather of the Middle West, the warm, dry weather of Southern California, and the foggy weather of San Francisco influenced it not at all; neither its spread nor virulence, nor the relative amount of pneumonia and mortality.

Propinquity and promiscuity are the predominat-

ing factors in its spread. Heiser,[11] in an interesting article on barrack life and respiratory diseases, quotes tables and statistics which seem to prove that men quartered under barrack conditions have an unusually high morbidity and a particularly high mortality from such infections—about double that of the general civil population. This was not confined to barracks which were obviously overcrowded, but obtained in barracks where there were 50 square feet of floor space per man, and where the ventilation seemed adequate. He states: "Experience based on laboratory investigations in our Army hospitals shows that in large wards the bacterial flora in the throats of the patients tended to become equal." That the same thing occurs among healthy men in barracks is quite inferential. It is analogous to an experiment in dialysis, or to water seeking its own level.

There are certain authors who go so far as to say that the pandemic of respiratory disease which we have passed through should be denominated epidemic pneumonia rather than influenza. They stress the fact that careful and accurate physical examinations by competent clinicians will show in the majority of patients in whom there are no obvious symptoms of lung involvement, one or perhaps more circumscribed patches of consolidation no larger, perhaps, than the bell of the stethoscope, located usually at the base of the lungs.

There are two questions that have cropped up many times in discussing the recent pandemic, and these are: Are we dealing with influenza, or is there a new disease and, Is the influenza outbreak a result of malnutrition arising out of the war? The *British Medical Journal*[12] settles these questions nicely, as follows:

> Influenza has customarily been considered as a specific disease like measles and scarlet fever, and some admit that it may be due to the same class of infectious agent; but with each recurring pandemic the notion that it is a new disease revives. The severity of the present pandemic, the suddenness of onset in some cases, and the number of deaths from pulmonary complications have led to the suggestion that the disease cannot be influenza but some other lethal infection. This is only because we have forgotten how severe a disease influenza may be. Peacock, writing of the epidemic of 1847, said that cases complicated by what he called capillary bronchitis were always very severe in character, and in debilitated persons proved fatal. Again, the suddenness of onset in this epidemic—persons being taken ill on the street—has been supposed to be something new, but Symes Thompson, writing of the epidemic of 1889, said: "In a number of recorded instances a violent attack of pain has been the first intimation, so severe sometimes as to cause the person to fall down under the impression that he had been struck." Another reason assigned for looking upon the epidemic as something other than influenza was that acute nasal catarrh was rarely observed during the summer. (This tallies with the symptomatology recorded in the American outbreak.) With the advent of colder weather, however, nasolaryngeal catarrh is now common. The very name, "Spanish disease," is not new, for the term was used as far back as the sixteenth century. The suggestion that the privations caused by the war are in some way responsible for the severity of the epidemic will not hold water. The disease has been little, if at all, more severe in Germany and Austria than in England or America, where the food restrictions have been much less, or in South Africa where they have been inappreciable. Such influence as the war has had is to be seen in the armies, and is to be traced to the congregation of large numbers of men in huts and billets and on crowded transports. It is fresh evidence, if that were needed, that the infection is disseminated by personal contact under conditions in which good ventilation is difficult or impossible.

When the recent pandemic hit Germany, in July, 1918, the question as to the identity of the disease with preceding influenza epidemics arose there, as elsewhere. It is recounted that the medical societies of Berlin and Munich held special meetings at which the identity of the prevalent disease with the last pandemic was agreed on by the majority of the authorities after detailed discussions. This recognition was made all the easier as, in characteristic German fashion, the pathological organs from lethal cases of the 1889 epidemic had been preserved, and were available for comparison with autopsy material from fresh fatal cases in which corresponding lesions were found to exist.

The mode of spread of influenza is so apparent that upon this subject all authorities are in agreement. Direct transmission from person to person of the infected secretions of the respiratory tract through forcible talking, sneezing, coughing, and spitting are the sources of infection; and to a less extent through infected things, hands, dishes, cups, glasses, and possibly napkins, in public eating or drinking places and in messes of military barracks and camps.

No authoritative suspicion has been raised that the lower animals or insects play any part in the transmission or spread of this disease.

Bacteriology.—Concerning the causative organism of influenza there are many different views and shades of opinion. On no other topic relative to the disease is the profession at such variance. A few still hold to the Pfeiffer bacillus as the etiological factor, but the majority of opinion, both abroad and in this country, is inclined toward some other germ or virus as the responsible agent. Some say a filterable virus, others a streptococcus or a pneumococcus, or a combination of these.

It is interesting to note that the peculiarly subtle nature of the outbreaks of influenza was recognized long before the bacteriological era, and indicated by the application of the name "influenza" to the disease, which means, literally, influence. The question of the nature of this "influence" has not been yet definitely settled, notwithstanding the fact that it has been hitherto generally accepted that Pfeiffer's bacillus was the etiological factor. In recent years the influenza bacillus has been found present in a good percentage of cases of whooping cough, measles, and scarlet fever; also in pulmonary tuberculosis and chronic bronchitis, which somewhat invalidates its claim. Moreover, in a large number of cases reported in the recent epidemic the influenza bacillus was not found regularly in the sputum, nor in the secretions of the respiratory tract. It is worthy of remark that in both the 1889 and the 1918 pandemics, French, German, and other investigators regarded the disease principally a streptococcus or mixed streptococcus and pneumococcus infection. It is apparent that about the only evidence to the effect that influenza is caused by the so-called influenza bacillus is the demonstration by Pfeiffer and others of the presence of this organism among the other bacterial flora found in the respiratory tract of patients ill with influenza.

There has been discovered no immune reaction,

that the writer has learned of, which would show that the body reacts definitely to the influenza bacillus in the course of the disease. As a matter of fact, there is no more real evidence in favor of the influenza bacillus being the etiological factor than can be adduced regarding several other germs found to be common inhabitants of the respiratory tract. Further, if the possibility that Pfeiffer's bacillus is the true etiological factor be granted, then wherein lies the essential difference between such strains and those found in cases of pertussis, measles, and other diseases? The *British Medical Journal*[12] has the following to say on the subject:

The *Bacillus influenzæ* isolated by Pfeiffer in 1892—that is, when the pandemic of 1889-90 had practically disappeared—has been generally accepted as the true virus, in spite of the fact that it was not found in widespread localized outbreaks, and that other organisms were found in many of them. The majority of the experts present at the conference summoned by the Director-General of the British Army Medical Service expressed considerable doubt as to the primary etiological significance of Pfeiffer's bacillus, and considered that the existence of some as yet undiscovered virus must be regarded as possible. The conference recognized that this bacillus is frequently present in the epidemic and plays some part in the production of the disease, but went on to point out that the organisms most frequently associated with it and chiefly responsible for the gravity of the secondary complications are pneumococci and streptococci.

Summed up, the post-mortem observations leave no doubt that the bacillus of Pfeiffer when present does not play any more important part than the ubiquitous diplostreptococci. Though secondary, perhaps, in point of time, these streptococci, some forms of which, at least, are hemolytic, are apparently primary in deciding the fatal issue, and seem to be transmissible from man to man equally with the main virus.

The idea that the severity of an epidemic of influenza is due to something in the nature of a symbiosis is borne out by the observations made in the cases of the New Zealand soldiers reported by Lieutenant-Colonel Macdonald. In his series of reported forty cases a considerable proportion were complicated by influenza, as Pfeiffer's bacillus was found in twenty-nine in which the sputum was carefully examined.

Of the suggestion that the true virus is a filter passer, it has been said that it is only a cloak to our ignorance as to its nature; though the results of some recent experiments by Nicolle and Lebailly, communicated to the Académie des Sciences, Paris, the other day by Professor Roux, Director of the Pasteur Institute, affords some evidence that a filter-passing virus does exist. The material used in these experiments consisted of the bronchial expectorations rich in a great variety of bacteria from a patient who had been suffering from influenza for three days. This was introduced into the conjunctivæ and nose of two monkeys—a bonnet and a macaccus. The bonnet monkey wasted and showed depression; the macaccus was less affected. The virulence of the secretions seemed proven by these experiments. The main experiments were made on human volunteers. The infectious secretions were shaken and dissolved in normal salt solution and filtered through a Chamberland bougie under pressure. A volunteer injected subcutaneously with the filtrate suffered a typical attack of influenza. The intravenous injection of a volunteer with 3 c.c. of blood taken directly from an influenza patient in the second day of a characteristic attack of influenza was negative. The conclusion was drawn that the infective agent of influenza is a filter-passing virus and that the virus does not circulate in the blood.

The varying, though not altogether conflicting opinions on the subject held by different authorities, both abroad and in America, are reflected in the following excerpts from the literature:

Regarding the absence of *B influenzæ* in the exudate from the upper air passages in the recent epidemic of influenza the British writers Little, Garfolle, and Williams[13] state: "In our cases studied we observed that direct smears from the nasopharynx, throat, and sputum contained one organism which was outstanding in its prevalence. It was a very small Gram positive diplococcus, distinctly flattened on its opposing sides. Some smears contained no other organisms. In no smears examined were we able to discover the *B. influenzæ*."

This coincides generally with what has been found by our American investigators, whose findings will be quoted later.

Regarding the bacteriological investigations in Germany, Beyer tells us: "The pandemic of influenza spared no part of Germany. The clinical picture was declared by German physicians to be identical with that of the last pandemic of 1889. Pfeiffer's bacillus has been found but exceptionally; streptococci and pneumococci were recovered from the sputum, the organs postmortem, and also from the blood of patients. Similar findings were recorded in 1899. Pfeiffer's bacillus was not found until 1902, though it should have been impossible to have overlooked it in 1889.

"Pfeiffer himself, it is said, has reserved his final opinion as to the relationship of the present pandemic with that of 1889-90. He had not examined a sufficient number of cases at Breslau, but had found his bacillus in some cases, while failing to discover it in others, and was still investigating the cause of his discrepancy.

"Gruber answered from Munich very simply: 'Influenza bacilli not found hitherto—investigations proceeding.'

"Ulrich Friedman, in charge of the infectious wards of the Virchow Hospital in Berlin, expressed his belief that the symptomology and complications of this pandemic correspond exactly with those described in 1889-90. He had not found the Pfeiffer bacillus, streptococci and pneumococci being the most common organisms encountered."

Of course, there is a possibility that the influenza bacillus may be evading capture on account of faulty methods of technique; yet, on the other hand, the possibility cannot be overlooked that there may be an epidemic disease clinically resembling influenza of which the Pfeiffer bacillus is not the agent.

Avery[15] reports the development of a selective medium for growing *B. influenzæ*—an oleate-hemoglobin agar—by the use of which Pfeiffer's bacillus can be recovered in cultures when ordinary means fail. The formula of his media is as follows:

Two per cent. meat infusion agar (0.3 acid to phenolphthalein) ..... 94 c.c.
Two per cent. solution sodium oleate (neutral) to make a concentration of 1:1000 with agar.. 5 c.c.
Suspension of red blood corpuscles (rabbits, sterile, defibrinated, and minus the serum).... 1 c.c.

On this medium the pneumococci and streptococci are inhibited, but it favors the growth of *B. influenzæ*, and also Gram-negative cocci of the *Micrococcus catarrhalis* group, staphylococci, and diphtheroids.

Dick and Murray[16] call attention to the fact that the influenza bacillus is pleomorphic. They cite the fact that Pfeiffer described a "true influenza" bacillus and a "pseudoinfluenza" bacillus which were culturally identical. Moreover, that he was unable to distinguish between these organisms in smears from exudates taken directly from patients. He based his distinction on the fact that smears from cultures of the true influenza bacillus appeared characteristically as small bacilli with few longer forms, while smears made from cultures of his pseudoinfluenza bacillus showed long, thread-like organisms. Dick and Murray, however, have proven to their satisfaction that these two types are but pleomorphic examples of the same organism. This pleomorphism being dependent upon the character of the media, *i.e.* in a slightly alkaline, neutral, or titrated not to exceed 0.2 acid media, the influenza organism grew in the short rod or bacillary form; but on media titrated acid in excess of 0.2 the organisms developed into a thread-like form resembling leptothrix. It is their conclusion that

where there is such variation in morphology in different cultures of the same strain, it does not seem justifiable to classify influenza bacilli as true or pseudo on the basis of morphology alone. Also, in attempting to isolate influenza bacilli it is important to recognize the leptothrix-like form as well as the small bacillary form.

Dr. James J. King[17] comes forward with the suggestion that owing to the similarity between the epidemics of pneumonic plague in North China and the recent influenza epidemic, they may be one and the same disease. Citing as reasons, first, that large numbers of coolies were brought from China to work behind the Allied lines in France who may have brought the infection with them; second, that the morphology of the Pfeiffer bacillus and *B. pestis* are similar (which is questionable), and concludes that the high mortality and infectivity of the recent pandemic suggests that *B. pestis* may have been present in the Chinese coolies in a nonvirulent form, and assumed a new virulence and a somewhat different form when transplanted into virgin soil.

It would take more than the presumptive evidence offered by King to convert the medical profession to the belief that what the people of the United States and elsewhere have been suffering from is pneumonic plague, with *B. pestis* as the etiological factor. The newspapers, always looking for something sensational, have echoed this supposition, and the laity have been quite ready to believe it. The medical profession has not taken it seriously, however.

The trend of opinion is in quite a different direction, as the following references will show:

Mac Lean[18] who studied outbreaks of influenza in three factories and an industrial school in Glasgow states that while the bacteriology of the disease has not been thoroughly investigated, two points have been satisfactorily established, namely: That Pfeiffer's influenza bacillus is invariably absent; but a Gram negative diplococcus resembling the pneumococcus has almost invariably been obtained from the nose, throat and lungs, and from the membranes of the brain in fatal cases.

An article by Muzum, Pilot, Strangel, and Bonar[19] describes the salient features of 2,000 cases of influenza admitted to the Cook County Hospital, Chicago, during five weeks of the epidemic period. The mortality of these cases was 31 per cent. They state that the influenza bacillus of Pfeiffer was isolated in only 8.7 per cent. of the total number of cases. Pneumococci were the predominating organisms in the sputum, throat cultures, and lung cultures taken after death. Experiments made with filtered nose and throat washings from influenza cases and injected into volunteers failed to produce the disease. They therefore conclude that influenza is not due to a filterable virus.

This is borne out by the results of the experiments of McCoy, Rosenau, *et al.*, described below.

Friedlander, McCord, Sladen, and Wheeler[20] examined 10,979 cases of influenza occurring among the troops at Camp Sherman, Ohio, in which there were 842 deaths, a mortality of 7.66 per cent. They report that *B. influenzæ* (Pfeiffer) was not found in a sufficient number of cases to give it credence as the causitive organism of the epidemic; the frequency of its detection not exceeding the frequency of its existence under normal conditions. They found the pneumococcus, chiefly type IV, the predominating organism. From the sputum this pneumococcus was recovered uniformly. In the necropsies this pneumococcus was detected in 53 per cent. of the cases. The hemolytic streptococcus occurred in 47 per cent. of thoracic exudates.

Reporting upon the bacteriological findings in influenza cases seen at the Puget Sound Navy Yard. Ely, Lloyd, Hitchcock, and Nickson[8] state that examinations of sputum from 49 early and 25 late cases showed that Gram positive cocci in pairs and chains, in company with streptococci predominated throughout all examinations. In a total of 52 attempts at blood culture on living patients, with 24 positive results, all gave streptococci save one in which there was a diplococcus. The streptococci were demonstrated to be one of the hemolytic type. From these and other findings they conclude: "The disease called inflfluenza at the Puget Sound Navy Yard was due to an organism which despite variations should be classed as a hemolytic streptococcus, at least until such time as the relationship between diplococci and streptococci is more accurately established. Our findings failed to show that the influenza bacillus of Pfeiffer was in any way connected with the production of the disease at this station."

Rosenow, 1919,[21] in a preliminary report states that his study of the secretions from the nose and throat and the sputum and lung exudate from the very beginning of the epidemic as it occurred in and about Rochester, Minnesota, revealed commonly among other bacteria a streptococcus, having the cultural features of the streptococcus viridane, and the smears often showed the organism in the form of a Gram-positive lanceolate diplococcus occurring singly but more often in long chains. He adds that the organism is undoubtedly the one found by English investigators and designated by them as diplostreptococcus.

Relating to the fact that pregnant women who develop influenza so often abort or die, one writer brings forward the theory that inasmuch as *Bacillus abortus* (Bang) is so closely allied to *B. influenzæ*, there is the possibility of their being one and the same, and therefore the former organism is possibly the etiological factor in the epidemic.

The difficulties surrounding the study of the nature of the virus of influenza are shown by the results of two series of experiments carried on jointly by the U. S. Public Health Service and the Navy, one series performed at the Boston Quarantine Station, and reported in *Public Health Reports*[42], of which the following is a brief summary:

Rosenau, Keegan, Goldberger, and Lake utilized 68 Naval volunteers at Boston. Various ones were inoculated with pure cultures of the Pfeiffer bacillus, with secretions both filtered and unfiltered from the upper respiratory passages, and with blood from typical cases of influenza. None of the volunteers showed any reaction from these inoculations. Thirty men were subjected to having their nose and throat sprayed and swabbed with both filtered and unfiltered influenza secretions but with the same negative results. Moreover 10 volunteers were exposed to the infection by allowing influenza patients to talk and cough in their faces, simulating ordinary contact. None of these volunteers developed any symptoms of influenza following this experiment.

McCoy and Richey at San Francisco utilized Naval volunteers, who differed from those at Boston by reason of not previously having been exposed to the disease, but who had been vaccinated with a bacterial vaccine containing Pfeiffer bacilli, pneumococci, and streptococci. The experiments were practically identical with those carried out at Boston, with the addition that a filtered emulsion of material from the upper air passages was dropped into the conjunctivæ of two volunteers. In all cases the results were negative, and in harmony with those at Boston. The only difference in reported results being that three volunteers subjected to the instillation in the nose of unfiltered secretions from the air passages of influenza cases developed acute tonsilitis from whom a hemolytic streptococcus was recovered on throat culture. Unfortunately these experiments are not conclusive, save in a negative way. It may be that the influenza patient is infective only in the very earliest stage of the disease.

This by no means exhausts the literature, as new reports are appearing weekly; but sufficient has been given to show the trend of thought and the results obtained during the recent pandemic of influenza.

Pathology.—There is but little to be said on this subject, as there is no characteristic pathological picture seen or described upon autopsy of influenza cases. After death from the pneumonia the picture is practically the same as seen in other bronchopneumonias. The size and areas of the consolida-

tions vary in different cases, and that is all. There is nothing added or subtracted by the influenza. Pus may be found between the lobes, or in the pleural cavity, but this is neither singular nor characteristic. The spleen is not ordinarily enlarged. The kidneys may show a state of cloudy swelling. The whole thing suggests that death is the result of a toxemia, with but few anatomical changes. Blood-cell counts during life almost invariably show a leucopenia, even as low as 3,000; but this, while characteristic of influenza, is not singular, as it occurs in other diseases. During the pneumonia a leucocytosis occurs, but this also occurs in all pneumonias.

Symptomatology.—Regarding the incubation period in influenza, all authorities are agreed that it is from one to four days, though in the great majority of cases it approximates very closely forty-eight hours.

The onset is sudden in most cases. A person going to bed feeling well may awake in the night or on the following morning aching all over. The suddenness of the onset has been touched on above in connection with other matters—instances of persons falling down in the street, under the belief that they had been struck, and the name signifying "a blow with a bar" given it by the Spaniards. As a rule, the development is not so precipitate as this. In some instances there is a distinct prodromal period of from one to four days, in which the patient feels somewhat chilly, is inclined to notice slight drafts, desires to remain in a warm place, and generally feels a loss of energy without actually feeling ill.

The following symptomatology, with slight variations, is agreed upon by all authorities as being characteristic of the disease in the common run of cases:

Onset rather sudden, with pains in the eyes, head, back, joints, and limbs. Chilliness without actual chills, and early marked prostration. A fever of from 101° to 104° F.; generally rather low than high. The pulse is relatively slow. Mental dullness, merging into drowsiness with somnolence, is characteristic. A coated tongue, with constipation, is usually the rule. After establishment of the disease the mucous membranes of nose and throat become reddened. Sneezing is not an uncommon nor yet an invariable symptom. Laryngeal involvement, with hoarseness and a dry, irritating, and unproductive cough, is generally present. An associated leucopenia is almost invariable. A leucocytosis points to some complication, most commonly a bronchopneumonia. In the ordinary cases the fever gradually falls to normal in three or four days, and more or less prostration and weakness is present for a week or two during convalescence. A transient albuminuria is not uncommon. Many cases have epistaxis and some have hemorrhages from the bowels. Premature menstruation is often brought on in females.

A broncho- or lobular pneumonia develops in such a relatively large proportion of cases as to make it a question whether we are dealing with the disease influenza, with accompanying pneumonia as a complication, or whether with epidemic pneumonia with prodromal symptoms suggestive of influenza. The latter is a speculative though tenable theory, albeit most physicians hold to the former as being the correct and natural viewpoint. At any rate, the lobular or bronchopneumonia which develops in from ten to thirty per cent. of the cases, according to different reports, is the condition responsible for most of the fatalities.

The pneumonia differs from the usual picture of clinical lobar pneumonia in that the temperature may be relatively low, and the pulse rate also, which gives but little indication of the seriousness of the condition. These cases, instead of subsiding, may come down to a practically normal temperature for a day; then there may be a sharp rise in temperature which is not accompanied with a rigor or any marked increase in the above mentioned constitutional symptoms. As a rule, in from 12 to 24 hours after the second rise of temperature physical examination will show, generally on the left side, small areas of consolidation at the base of the lung about the size of a dollar. In those that recover the condition becomes stationary at this point and resolution takes place in a remarkably rapid manner.

In the fatal cases, by the second day following the secondary rise of temperature the areas of consolidation are scattered through both lungs. Some cases in the recent epidemic went on to a massive lobar consolidation, accompanied by the symptoms found in the usual lobar pneumonias, save only that the pulse rate remained disproportionately low; and likewise the respiration rate. Cases with almost complete consolidation of the lung as to the lower lobes, with a temperature possibly as high as 104° or 105° F., may have a pulse around 100, with respirations of but 24 to 26. Such cases, however, generally develop a profound toxemia, with vasomotor depression, closing with death.

A few of the more or less rare and anomalous symptoms reported as observed during the recent pandemic will be mentioned. Cyanosis, or a dusky or ashen hue of the skin, could hardly be considered rare, as a number of writers referred to it. Stupor in severe forms resembling the typhoid state is spoken of in some cases.

Hemorrhages of various kinds have been striking manifestations of the disease in the recent epidemic. McConnochie[22] on this subject says: "Epistaxis is an unusual symptom, but frequently seen in both children and adults in this epidemic. Hematemasis is frequent in those cases in which vomiting occurs. Hemoptysis is present in the pneumonia stage, but I have seen it in four cases in whom there was no pneumonia, and all of whom were up and out in a week. Young girls menstruate before their time, and girls who have never menstruated commence that function during an attack. Pregnant women miscarry in nearly every instance."

Erskine and Knight[23] mention hemorrhage from the bladder and from the bowels, also bleeding from the gums. Several of their young patients developed hemorrhagic purpura, and they state that many of their pneumonia cases coughed up bright red blood, some of them dying suddenly from asphyxia due to active hemorrhage.

Osler says influenza is a disease of protean aspects, and to recount fully the varied symptomatology which has at one time or another been observed would unduly prolong this paper.

Complications and Sequelæ.—These will be but briefly touched upon.

Mackenzie[24] described various complications of the nervous system seen in his cases. Neuritis, diffuse and local, and herpes zoster were noted. He mentions seeing a case with neuritis of the fifth, seventh, and eighth nerves, with herpes of the external auditory canal and tympanic membrane. This latter symptom he considers pathognomonic of influenza. He reports otitis media not uncommon, occurring in from one to three per cent. of his cases.

Regarding kidney complications, Case[25] reports that uranalyses in 225 cases of influenza showed albumin in 150, and in 83 casts were found, indicating a very distinct kidney irritation from the toxemia.

Sabshin[26] mentions unusual skin complications. He saw half a dozen diffuse erythemas, in one of which the rash would come and go, with red areas two inches in diameter. Some of the protracted cases had scarlatina form rashes all over the body. He states that supraorbital neuralgia occurred in three of his cases; neuritis of the lower extremities in one, and otitis media in ten per cent. of his 450 cases.

Worthington[27] describes a curious sequel to influenza. Sharp, rhythmic pains in the left upper quadrant of the abdomen occurred in five of his convalescent cases. The duration of these pains was said to be less than 24 hours, and though severe while they lasted the prognosis was good.

Defluvium capillorum (falling out of the hair) was reported by one author.

As indicating the seriousness of influenza pneumonia when complicated by pregnancy, Woolston and Conley[28] relate their experience in a series of 101 cases of pregnant women who developed influenza pneumonia in whom there occurred 52 deaths, a mortality of 51.4 per cent. In 75 per cent. of the fatalities abortion occurred on an average of 24 hours preceding death.

Treatment.—The modes of treatment are almost as varied as the number of physicians called upon to treat the cases. While no standard treatment has been developed, a majority are agreed upon certain points which will be touched upon below. That so many different modes of treatment are advocated and such an array of drugs prescribed is sufficient evidence that no one method or drug has been recognized as of preeminent value. That from 80 to 90 per cent. of those attacked with the disease recover with any or no special treatment is also good evidence of the lack of specificity of any particular remedial agent. Human immune blood serum in influenza pneumonia is the one exception to the above statement; but for obvious reasons it seems likely that this serum will not become commercially available, or securable in sufficient amounts, to effect much impression on the end results of an influenza epidemic.

The usual treatments prescribed may be classified as general and symptomatic; drugs, vaccines, and human immune blood serum.

The profession is pretty well agreed as to the usefulness of the following general and symptomatic measures of treatment:

The patient is to be kept in bed, well covered, in a warm but properly ventilated room until at least three days have elapsed after the temperature reaches normal. Chilling is to be avoided. The bowels are to be kept open and the mouth kept clean, and elimination favored by the free ingestion of water.

One of the coal-tar analgesics may be used with discretion in controlling the myalgias and other pains. The strength is to be conserved with an adequate amount of nourishment in an easily digested form. As to the pneumonias, of which 50 per cent., on an average, result fatally, beyond the patient's initial power of resistance, nothing seems to avail unless it be the human immune serum. It is the toxemia mainly that has to be combated, and without a specific serum we are powerless to overcome its lethal effects, save to favor elimination and at the same time support the system and conserve the patient's strength. The introduction of fluids into the body by mouth, by proctoclysis, or even hypodermoclysis, tends to combat the toxemia and to favor elimination of toxins. Marked cyanosis is an extremely unfavorable symptom, and demands the use of oxygen. Prostration is to be combated with caffeine, digitalis, strophanthus, or camphorated oil, usually given hypodermically. Large doses of morphine or atropine may be required.

If the virus or germ productive of the disease were definitely established and a specific antitoxin could be produced, the problem would be solved. This is lacking, however, and aside from the monkey, perhaps none of the lower animals seem susceptible to the disease, which precludes the production of antitoxin by the usual means. Hence convalescent blood serum, either pure or citrated, offers the only hope, particularly in the pneumonias.

It might be of interest, however, to recount briefly the various remedial agents for which the writers claim benefit as published in the literature.

A number of British writers pin their faith to salicin, for which they claim beneficial results. An English physician[29] is quoted who treated 2,000 cases of influenza with 20 grains of salicin given every hour, who not only advocates it as a curative measure but believes that the saturation of the system with salicin abolishes the infectivity of the patient.

It is also stated that another English practitioner (C. Ross) recommends the use of 5 drops of the oil of cinnamon, B. P., in a tablespoonful of water every two hours until the temperature has become normal.

Beverley Robinson of New York recommends salicylate of ammonium 0.33 every two hours.

A number of men have lauded the free exhibition of quinine as productive of benefit, especially as a prophylactic.

To counteract the hemorrhagic tendencies of the disease, Erskine and Knight[23] tried large doses of calcium lactate, which they believed gave good results, and also remarked that there seemed to be fewer hemorrhages in their pneumonia patients who took calcium iodide to control their cough. They also suggest the use of horse serum as likely to prove beneficial in controlling the hemorrhagic condition, as in their opinion the hemorrhages noted seemed to be the result of a lessened power of coagulability of the blood. They timed the coagula-

tion of blood in a number of these cases, and the increase in time was in every instance from two and one-half minutes to eight minutes longer than the normal.

The alkali treatment of influenza was advocated by several authors to combat the acidosis which they believed was brought on by the disease. Its use both per os and per anus was recommended; by the latter route, either in the shape of large enemas, or intrarectally with the addition of glucose by the Murphy drip method. Ely of Philadelphia[30] is enthusiastic in advocating the alkali treatment in influenza. He used large doses of sodium carbonate, potassium citrate, and lime water by mouth every two hours. In his opinion a number of his patients were so desperately ill that they could not have recovered without the basic treatment by the alkalis upon the acidosis theory.

Several physicians have spoken highly of the use of adrenalin to combat the asthenia and circulatory depression so evident in influenza cases.

Von Tiling[31] reports seeing several cases during the epidemic who presented almost the classical symptoms of Addison's disease: extreme muscular weakness, tendency to syncope, insomnia, low diastolic pressure, with high pulse pressure, and a brownish appearing skin. He believes that the extreme prostration, with weakness, so often seen in influenza both during the attack and in convalescence, is due not so much to a weakened heart muscle as to adrenal insufficiency. He claims beneficial results from the administration of suprarenal gland substance, and recommends its use to others.

Vaccines.—The use of bacterial vaccines as a prophylactic agent has been the chief subject of discussion, but the therapeutic use of vaccines of one kind and another is not without advocates.

In this connection, with probably especial reference to Pfeiffer bacillus vaccine, the Massachusetts Board of Investigation, appointed early in the epidemic, composed of Rosenau, Gay, and McCoy, concluded as follows: "The evidence at hand convinces the board that the vaccines we have considered have no specific value in the treatment of influenza."

A second committee, known as the Special Board of Statistical Investigation, composed of Whipple, Davis, and Crum, reported: "The weight of such statistical evidence as we have been able to accumulate indicates that the use of the influenza vaccine which we have investigated is without therapeutic benefit." So much for the remedial use of *B. influanzæ* vaccine.

Edgeworth,[32] a British writer, reports 15 cases of influenza in which antistreptococcus serum was given hypodermically in 10-c.c. doses, in which all recovered and no pneumonias occurred. But he adds: "I have not had any good results from the serum in four cases where pneumonia had already developed." Edgeworth's cases are entirely too few to warrant drawing any conclusions. It is quite possible that his 15 cases would have recovered without pneumonia with any other form of treatment, and the antistreptococcus serum withheld. However, it would seem that the antistreptococcus serum treatment of a large number of cases in a military cantonment, for instance, where, as a rule, the pneumonia incidence is high, would be worth trying; and the results in hundreds or thousands of cases could be compared with an equal number in other camps treated without this serum, to note the relative number of developing pneumonias in each instance. A reasonably accurate conclusion as to the efficacy of streptococcus serum in the premises could then be drawn.

That the treatment of influenza pneumonia with human convalescent blood serum is a valuable contribution to the therapeutics of this disease is proved by the rather extensive experience reported by various authors. The only drawback to its most effective use is that it is, or would be, not ordinarily available save in time of epidemic, and probably then only in good-sized, well-equipped hospitals.

The measure of success and means of using human convalescent serum are shown by the following: McGuire and Rudden[33] treated 37 cases of influenza pneumonia by the use of convalescent human serum at the Chelsea Naval Hospital with good results; all but one case recovered. The immune serum was secured by bleeding convalescent patients within 7 to 10 days after their temperatures had dropped to normal. Four hundred c.c. of blood was drawn on two successive days, 800 c.c. from each patient. Wassermanns were done on all donors preliminary to taking their blood; and compatibility tests were performed with donor's serum and recipient's corpuscles. From 75 to 100 c.c. of immune serum was the average dose administered. The prompt improvement within 12 hours of the patient's condition was generally manifest, though in about 15 per cent. of instances the serum was found to be lacking in antibodies, necessitating the trial of another convalescent's serum. No success was had in the attempts made to test the potency of the serum by complement fixation and by gross agglutination, using recently isolated influenza bacilli as an antigen.

They state: "Experience has shown that most beneficial results will be obtained by giving the immune serum within the first 48 hours of the pneumonia complication. This mode of treatment requires the assistance of a well-equipped laboratory and competent technicists.

O'Malley and Hartman[34] treated 46 cases of influenza pneumonia with human convalescent blood plasma with but three deaths, a mortality of 6.5 per cent. Of 111 cases coming under their control who were not treated with the immune plasma 28 died, a mortality of 25.2 per cent., or about four times the percentage of mortality as among those receiving the benefit of the human immune plasma.

Their conclusions were: (1) The toxemia of influenza seems to be neutralized by the plasma from convalescent patients. (2) With the exercise of certain care the tests for compatibility can be eliminated. (3) While a large percentage of all convalescents' blood plasma is active, most satisfactory results are obtained by pooling the different lots. (4) Sharp reactions are followed by the most prompt improvement, but are not essential to success. (5) Pneumonia must be diagnosed early and treated immediately if a large percentage of recoveries is to be obtained.

Maclachlan and Fetter[35] used the citrated blood from human convalescents with success. Summarized, their conclusions were: The use of citrated blood from convalescent influenza patients when ad-

ministered to patients suffering from the pneumonia following influenza appeared to have a decidedly beneficial effect, particularly if used early. Beyond the third day of the pneumonia it was of little value. That the citrated blood establishes an immunity to *B. influenzæ* is inferred but not proved.

Prophylaxis and Suppression.—The subject of prophylaxis divides itself into personal and general. Under personal prophylaxis there presents for discussion the use of drugs, vaccines, and face masks.

The only drug worthy of mention which has been advocated as a prophylactic agent in influenza is quinine. Regarding the usefulness of this drug Frankel[36] says: "I find quinine of great and almost specific value as a prophylactic measure in the latent stage of grippe or influenza. Its use in from 10 to 20 or more grains daily for a few days will invariably abort an impending acute attack, and frequently ward off dangerous complications." He further urges its universal use as a prophylactic measure by all persons during an influenza epidemic.

Vaccines.—Here we enter upon a much mooted subject. With the possible exception of the causative germ, no other subject connected with influenza has been productive of so much discussion and controversy.

Early in the epidemic in America Dr. Timothy Leary[37] of Boston manufactured a vaccine from three strains of influenza bacilli which he advocated to be used both prophylactically and therapeutically. Being the first in the field and at a time when all the symptoms, complications, and sequelæ were generally believed to be due to the Pfeiffer bacillus, it received wide publicity and usage.

Various City Health Departments secured for free distribution in their cities thousands of doses of this vaccine, in an effort to stamp out the disease.

The Public Health Service was sufficiently interested to send Surgeon G. W. McCoy, Director of the Hygienic Laboratory, to Boston to investigate the claims of Leary and others, as the whole country was awaiting an announcement by the Service of some agent which would receive the official stamp of being efficacious in eradicating the disease. Unfortunately it was found that its usefulness was not all that had been claimed for it, and further by its use a false sense of security might be engendered whereby people would omit such safeguards as the wearing of masks and avoidance of infected persons. Indeed, in the light of the later bacteriological findings in the disease it is not surprising that its efficacy was not considered proved at the time, and later findings confirmed the judgment rendered.

As to the prophylactic value of Leary's vaccine, Barnes[38] reports that it was administered as a prophylactic measure to 172 employees and patients in the Rhode Island State Sanatorium with doubtful results. Out of 90 vaccinated persons who were subsequently exposed to infection with influenza 24 developed the disease, an incidence of 26 per cent.; while 64 unvaccinated persons furnished 22 cases, an incidence of 34 per cent. In 25 influenza cases following vaccination 4, or 16 per cent., died; while in 57 cases among the unvaccinated the mortality was 9, or 15.8 per cent. He concludes that the morbidity was only slightly lower among the vaccinated and the mortality among those who developed influenza was practically the same whether vaccinated or unvaccinated.

Mixed vaccines have been prepared by various physicians using the more common strains of organisms found in the respiratory tract in influenza, either with or without the inclusion of the Pffeifer bacillus, which have given more promising results.

Rosenow[21] prepared a mixed vaccine having the formula given below, for which he claims decidedly beneficial results when used as a prophylactic agent. His vaccine contained the following:

Pneumococci, Types I (10 per cent.), II (14 per cent.), and III (6 per cent.) . . 30 per cent.
Pneumococci, Group IV, and the allied green-producing diplostreptococcus . . . 30 per cent.
Hemolytic streptococci . . . . . 20 per cent.
Staphylococcus aureus . . . . . 10 per cent.
Influenza bacillus . . . . . 10 per cent.

He reports 20,792 persons inoculated with this vaccine in whom the incidence was only one-third as great among 61,753 persons under surveillance who were uninoculated; the death rate being only one-fourth as great in the former as the latter. Moreover, he states that at the State Hospital for the Insane at Rochester, Minn., with a total population of about 1,500 where one case of influenza had developed before the inoculations with this vaccine were given, only three cases occurred following the date of the inoculation for a period of six weeks. This is qualified by the statement, however, that with the occurrence of a second wave of the epidemic, a mild outbreak of the disease took place at this institution, which seems to indicate that the immunity engendered by the vaccine is of short duration.

Ely, Lloyd, Hitchcock, and Nickson[8] made a vaccine from mixed virulent strains of hemolytic streptococci isolated from blood cultures of influenza patients during the epidemic at the Navy Yard near Seattle, and with its use obtained the following results: Of 4,212 men who were vaccinated not one died. Among 111 Filipinos isolated and vaccinated early and later exposed there occurred but 2 cases. Among 361 marines vaccinated early with no attempt later to control exposure there were but 2 cases, both patients coming down after the first injection. Both men recovered. Altogether there were 1,279 men who were vaccinated either before exposure or about the time they were exposed, and of these 94 developed the disease before the series of vaccinations was completed, and 11 afterward—a total incidence of about 6 per cent. All recovered.

Their conclusions in the premises were as follows: "We believe that the use of killed cultures of streptococci isolated from fresh human cases prevented the development of the disease in many of our personnel, and modified its course favorably in others. We suspect that there may be different strains of organisms causing influenza (call it what you please) and recommend for vaccines cultures recently from human tissues, preferably from cases in the same community where the disease is prevalent; such cultures must kill rabbits promptly when given intravenously. We offer no suggestion with regard to the duration of the immunity produced, but in our experience the vaccination may be repeated without inconvenience."

So much for bacterial vaccines as a prophylactic in influenza.

The use of face masks by physicians and nurses to prevent incurring contagious diseases through droplet infection is not new, though this measure probably has not been accorded the recognition its value warrants. It is capable of use both individually and generally. Through the beneficent results that accrued from the wearing of gauze face masks in the recent influenza epidemic and the wide advertising of the same that ensued, it is highly probable that they will be more frequently and generally worn in the presence of cases or epidemics of diseases of the respiratory tract in the future.

Doust and Lyon[39] carried out a long series of experiments under controlled conditions to determine the efficacy of gauze face masks of varying thickness in preventing the dissemination of bacteria. By taking suspensions of *B. prodigiosus* into the mouth and sitting before a table on which sterile agar plates were exposed at various distances, and talking and coughing through gauze masks of varying thicknesses they arrived at the following conclusions: "A three-layer butter-cloth mask is efficient in preventing the projection of infectious material from the mouth during speaking and coughing. It is a suitable mask, therefore, to be worn in connection with respiratory diseases."

It is a reasonable corollary to deduce from their experiments that if the infected subject or carrier and the noninfected person both wore three-ply butter-cloth face masks when in contact, the protection afforded the noninfected would be doubly efficient and secure. In other words, during an influenza epidemic if every one would, or was required to wear a face mask of that character the transmission of the infection from those in the incubation period, sick, convalescent, or from well carriers to the healthy noninfected population would be greatly minimized.

Minor[40] recommends for cosmetic and sanitary reasons instead of a gauze face mask the use of a gauze nasal filter or pledget. This is to be made of three thicknesses of gauze an inch square, folded into a cone shape and inserted into each nostril. When soiled, the same is to be discarded and a new one made and used. He recommends this as being cheap, simply and easily made, and inconspicuously worn, claiming all the benefits of the gauze face mask with none of its disadvantages.

Measures of General Prophylaxis.—There is no question in the mind of the writer as to the efficacy of the gauze face mask not only as a useful provision in personal prophylaxis, but one that is capable of being used effectively by the general public in preventing the spread of influenza during an epidemic. It was the writer's privilege to witness a public experiment or demonstration of this in San Francisco during October and November, 1918. Late in October, soon after the epidemic began in that city, the Board of Supervisors, upon the recommendation of the Board of Health, passed an ordinance requiring in effect that all persons must wear a gauze face mask at all times when outside their own homes. Persons found not compliant were subject to arrest and a fine, as in other misdemeanor cases. It was rigidly enforced, and in the beginning a number of persons were arrested and fined; but the observance was practically 100 per cent. perfect, the citizens as a rule submitting gracefully without complaint. As a result, where there had been 2,000 new cases in the city the day the ordinance went into effect, within three days thereafter there was a marked diminution in new cases, which continued to decline as long as the masks were consistently worn. While the disease was declining, but before it was entirely stamped out, the amusement interests, churches, Christian Scientists, and others whose places had been closed to the public, brought such pressure to bear that the Health Department was constrained to become acquiescent. Public gatherings were again allowed first with masks, and soon without, and after the ordinance had been in effect about one month it was repealed. However, in this time the measure had demonstrated its efficiency: first in the rapid decline of the incidence curve, and second that the epidemic had lasted only about a month in San Francisco whereas its prevalence in other large cities was six weeks or over.

There were, of course, many convalescent carriers in the city, and these were daily augmented by arrivals from outside, so the expected happened. Due to the opening of places of public entertainment, and without the protection of the masks, in about a month from the time the masks were discarded influenza was again epidemic in San Francisco and the second wave threatened to become more severe than the first, as the susceptible material in the city was far from exhausted in the primary wave. The Health Department in January, 1919, was forced to urge the Supervisors again to pass the masking ordinance as the only weapon that offered hope in controlling the spread of the disease. At the time of writing the success of the second public masking as a prophylactic and suppressive measure in San Francisco has not been learned.

As a matter of general prophylaxis the public should be instructed that every person as soon as he feels himself becoming ill with the disease should go home and to bed and stay there until recovered. If this was invariably observed it would not only go far toward controlling the spread of the disease, but would have a tendency to diminish the mortality. Too many people, not realizing the gravity of influenza, remain up, often using alcoholic stimulants in an effort to maintain themselves in their accustomed routine, and so continue until actually too ill to sit up any longer, continuing to disseminate the infection meanwhile, and jeopardizing their own chances of recovery.

Proper publicity both in the press and through medical consultants that the people may become enlightened as to the dangers to themselves and others by this procedure, should be carried out. This would, of course, not control the "carriers" of whom there must be many in every epidemic; but the requirement of wearing face masks when abroad while in association with other people on street cars and the like would minimize the danger from "carriers."

Quarantine has been resorted to in a number of places during the recent epidemic with questionable benefit in so far as controlling the spread of the

disease is concerned. It is extremely doubtful if quarantine procedures can be sufficiently rigidly enforced in a large city during the presence of an epidemic the size of that in 1918 to do any good. It was an effort, of course, to do something that offered any hope in controlling the spread of the disease.

The Illinois Department of Health ordered that all influenza patients must be quarantined until all clinical manifestations of the attack had subsided and the temperature had been normal for three successive days.

It was reported that in New York City influenza patients were quarantined, and further that "the City Health Department is prepared to compel patients who may be so situated as to be a menace to the community to go into hospitals."

The Navy Medical Corps considered quarantine impracticable, but all influenza patients were put to bed as soon as the diagnosis was made, and the patients in the wards were segregated by means of sheet screens between the beds.

Lynch and Cumming[43] advance the opinion that a significant factor in regard to the spread of influenza in military camps is the inadequate washing of mess kits. They believe that hand to mouth infection is equally as important in spreading the disease as face to face or man to man infection. This is worthy of consideration, and it is easy to postulate that in civilian communities health officers should enforce, if not the sterilization, the thorough washing in hot water and soap and subsequent drying after usage of dishes and other eating utensils at lunch counters, restaurants, and other eating places, and the same regarding glasses, etc., at soda fountains and in saloons.

The report made by a special committee on influenza of the American Public Health Association[44] with especial reference to prevention and the administrative measures that should be taken to afford relief and suppress the disease during a time of epidemic is so particularly excellent and timely that it is regretted that it cannot be quoted in full here.

Certain measures, however, particularly applicable by city or State health departments not previously touched upon in this paper will be given in the following outline:

Administrative Preventive Measures.—I. Efficient plan of organization to meet the emergency providing for a centralized control and coordination of all resources.

II. Machinery for ascertaining all facts regarding the epidemic.

III. Publicity and education with respect to respiratory hygiene.

IV. Health ordinances and regulations: (A) Laws against common drinking cups, etc. (B) Proper ventilation laws. (C) The closure of public meeting places:

Schools: To be closed only after consideration given whether adequate medical inspection exists, and whether the children are more liable to contract the disease out of school than in.

Churches: Services to be reduced to the minimum. (In California this question was solved by holding open-air services.)

Theaters, dance halls, saloons, and pool rooms to be closed.

Street cars: Ventilation and cleanliness to be insisted upon. Overcrowding discouraged. Staggering of opening and closing hours of stores and factories to avoid congestion on cars.

Funerals: Public funerals prohibited.

Masks: Their use to be recommended, especially by those in contact with the sick.

Isolation of influenza cases to be insisted upon. If not carried out, quarantine to be imposed.

Hospitalization: For those persons who cannot be satisfactorily isolated and treated in their own quarters, hospitalization should be mandatory.

Sprays and gargles: Not to be recommended as these fail to protect against infection.

Administrative Measures for Relief.—I. Reporting of all cases and deaths must be made compulsory.

II. Listing and distribution of all resources: Physicians, nurses, social workers, nurses' aids, clerks, domestics, laundresses, automobiles, chauffeurs, mask makers, and volunteer workers of all kinds should be listed, preferably in advance of the epidemic.

City should be districted, with a director and adequate personnel detailed to each district.

III. Current and continual analysis of the case situation in each district and in the city as a whole should be kept up during the epidemic.

IV. Organization: (A) Field Nursing: Arrangement made for securing and training adequate field nurses. (B) Emergency Medical Service to be arranged for. (C) Hospital Facilities: These to be arranged for and facilities kept ahead of the demand.

V. Plans made for social relief measures. (A) Through Red Cross facilities. (B) Through charitable organizations.

VI. Food. Central cooking facilities to be made available.

VII. Provision of laundry facilities.

VIII. Provision for fatalities. Arrangements to be made that will insure prompt disposal of bodies.

IX. Education, instruction and publicity.

X. It is finally suggested that every city health department draw up a program based on the foregoing outline, holding it in reserve for future use, if not in immediate need, modified to fit the size and other characteristics of the particular community.

Summary and Conclusions.—1. That the Pfeiffer bacillus plays more than a contributory rôle, if any, in the disease known as influenza has not been established; and that it is the causative organism for the symptom-complex seen in influenza has been practically disproven.

2. There is some evidence that the Pfeiffer bacillus may prepare the soil for the growth of certain streptococci and pneumococci which seem to be the agents principally responsible for the fatalities; but further evidence and observation along this line are needed.

3. The evidence regarding the presence of an infective filterable virus in influenza is inconclusive; rather the weight of evidence on this subject at the present time is in the negative.

4. There is favorable evidence that mixed bacterial vaccines, including streptococci and pneumococci isolated from fresh cases, are useful and

worthy of trial in the prophylaxis of the disease.

5. The early use of human immune blood serum from recent convalescent cases in influenza pneumonias has given good results, and where available warrants more extended trial and report in the future.

6. The results derived from wearing gauze face masks, particularly those made of three-ply buttercloth, are such as to justify their use as a preventive measure not only by those in direct contact with the sick, but by all persons, mandatorily, during the presence of an influenza epidemic. The gauze face mask should not be depended upon as a sole protection, but as an adjuvant to all other measures of prophylaxis.

7. The past history and present outlook regarding influenza constrains all health organizations to secure the proper plans, laws, regulations and appropriations requisite to render relief and to eradicate the disease.

QUESTIONS IN RELATION TO THE TREATMENT OF PERIPHERAL NERVE INJURIES.*

BY W. WAYNE BABCOCK, LT.-COLONEL, M.C., U. S. A.,
AND
IRVING J. SPEAR, MAJOR, M.C., U. S. A.
FT. MCPHERSON, GEORGIA.
GENERAL HOSPITAL NUMBER SIX.

ABOUT four hundred and twenty patients with evidence of peripheral nerve injury were admitted to Ft. McPherson between Oct. 1, 1918, and June 1, 1919. Over five hundred and ten nerve lesions were studied in these patients, and three hundred and twenty-eight operations upon peripheral nerves were performed. Over half of the injured nerves (165) were subjected to neurolysis, usually with hersage and 163 complete or partial divisions of nerve trunks were treated by suture.

In our series the ulnar nerve stands first in order of frequency with 103 involvements and 81 operated cases, the musculospiral second, 85, with 49 operated, the median nerve third, 75, with 56 operated. About 65 per cent. of our patients have been subjected to operation.

A careful statistical study made by Major Irving J. Spear shows that the patients subjected to operation, have made better and more continuous progress than the less serious cases that have been treated only by massage, electricity, and so forth. In a series of 75 cases treated by hersage, it was found that although a few of these patients were temporarily made worse by operation, at the end of two or three months they had regained all that was lost, and usually had a decided improvement. After neurolysis, while a few patients had a very rapid

*Read at the twentieth annual meeting of the American Therapeutic Society, June 7, 1919.

improvement, in a large proportion the improvement has been slow—almost as slow as after suture. No immediate improvement after suture has been observed, or is to be expected; but as a rule the progress in these cases corresponds to the estimated penetration of a neuraxes at the rate of 1 mm. per day beyond the point of suture. The partial splitting of a nerve trunk in its component bundles and the rerouting of the nerve filaments through muscle, intermuscular planes, or under subcutaneous fat, does not seem to jeopardize function.

The following is a summary of the nerves involved and the types of operation performed up to June 1, 1919.

Operation	Suture	Neurolysis	Total
Ulnar	44	37	81
Median	17	39	56
Musculospiral	24	25	49
Sciatic	29	16	45
Brachial plexus	4	10	14
Post-tibial	4	2	6
Anterior tibial	4	2	6
External popliteal	12	10	22
Internal popliteal	3	1	4
Anterior crural	0	1	1
Cutaneous branch	1	0	1
Internal saphenous	2	0	2
Internal cutaneous	4	4	8
Musculocutaneous	7	10	17
Circumflex	0	1	1
Radial	3	1	4
Facial	1	1	2
Posterior interosseous	0	4	4
Anterior interosseous	1	0	1
Spinal accessory	0	1	1
Internal plantar	1	0	1
Middle cutaneous	1	0	1
Muscular branch	1	0	1
Totals	163	165	328

The following questions and answers briefly summarize our present conclusions in regard to the treatment of peripheral nerve injury.

I. *Diagnosis.*—1. What relative values are to be ascribed to the various methods in diagnosing injuries of peripheral nerves?

Answer: The most important evidence is obtained from the sensory and motor loss; the former is determined chiefly by mapping the loss to tactile and painful impressions; the latter by studying voluntary contractions in muscles. Deep pressure tingling is of value in determining the penetration of sensory neuraxes, but has little quantitative or motor value.

Electrical reactions may be misleading in the preliminary examination, and the electrical return so lags behind the sensory and motor return as to have little value in determining regeneration. Deep pressure, vibration, and thermic change are of scientific rather than practical value, as are also the results obtained by the condensor apparatus.

2. What are the indications for operative intervention?

Answer: (*a*) A persistent total or partial interruption in a nerve.

(*b*) Doubtful nerve lesions in which careful study has shown the desirability of exploration. A carefully performed exploratory operation is nearly free from harm, and often is of great value to the patient.

3. Are reoperations justifiable, and when?

Answer: After neurolysis, the absence of improvement after proper postoperative treatment for three months—sometimes after one month—justifies reoperation. After neurorrhaphy and nerve grafting reoperation is justified if twice the normal time for neuraxes to penetrate from the lesion to the periphery has elapsed without evidence of regeneration. Rapid improvement may follow a reoperation neurolysis and suture removal in a suture case, or the operation may show a condition in urgent need of correction.

4. At what rate should regeneration occur after nerve suture:

Answer: Neuraxes should penetrate the nerve trunk distal to the line of suture at the rate of about one millimeter each day, or about one inch a month.

5. How long should operation be deferred after the healing of gunshot wounds to avoid residual infection?

Answer: Superficial granulating surfaces do not contraindicate immediate operation in our experience, provided the granulating surface is properly sterilized by a thorough preliminary application of saturated zinc chloride solution. If the adjacent skin is then carefully cleansed, the scar and granulating area excised en masse, and all instruments changed, the operation may proceed as usual, with little increased risk of infection.

Much greater danger comes from exposing or operating upon bone that has been the seat of compound fracture or osteomyelitis. Even if the wound has been healed for three months, there is danger of infection from invading the bone. It is, therefore, usually wise to operate upon the bone at a separate time. Deep infection adjacent to a nerve, however, does not always prevent nerve regeneration. Thus, in one case, where infection and prolonged drainage followed suture of the musculospiral nerve and an associated operation for compound comminuted fracture of the humerus, the nerve sequestered in muscle, showed motor return in the normal time, *i.e.* the man had return of extensor power to the wrist at the end of five months.

6. In case of associated soft tissue, bone and nerve injury healed, which lesion should be considered first?

Answer: If the nerve is an important one it should have first consideration. The associated condition should not be permitted to cause harmful delay in operating upon the nerve; other departments should not be permitted to withhold such a case from the department of neuro-surgery.

II. *Operative Technique.*—7. What operations are permissible for nerve injury?

Answer: Only four: end-to-end suture, neurolysis, and nerve trunk exploration, hersage or nerve fiber dissassociation—and in very rare cases, nerve grafting. Nerve flaps, lateral implantations, and substitutions should not be employed.

8. What should constitute a neurolysis?

Answer: The careful freeing of a nerve trunk from constricting or compressing tissue. It is important to determine the existence of sufficient fasciculi through the area of injury. If the fasciculi cannot be seen through the nerve sheath, the sheath should be split longitudinally, and the nerve substance explored until the surgeon knows the limits and degree of nerve injury. This is very important. It is not enough to isolate a cord that resembles a nerve trunk—there must be proof that there is no anatomical block. The separation of

fasciculi by careful exploratory incision into a nerve should produce no demonstrable reduction in nerve conduction, and often is invaluable in deciding as to the necessity of nerve resection and suture. In our opinion, the general failure to have explored exposed damaged nerve trunks, will be responsible for many operative failures and many reoperations. To further prove that neurolysis is a sufficient electrical conduction tests made during the operation have much positive, but litle negative value.

9. What is the relative percentage value as to functional return after (*a*) suture; (*b*) nerve grafting?

Answer: (*a*) We can only express an opinion, final statistics not being available; after nerve suture, at the least eighty per cent.; after nerve grafting, at the most five per cent.; the percentage being higher in operations upon the musculospiral and external popliteal, and less with the ulnar and internal popliteal nerves.

10. What length of gap in the various peripheral nerves may be treated by end to end suture, without resort to grafting?

	Cms.
Cords of brachial plexus	7
Ulnar in arm	13
Ulnar in forearm	13
Ulnar in forearm without transposing to front of elbow	5
Median in arm	12
Median in forearm without transposing to subcutaneous position	8
Median in forearm by transposing to subcutaneous position	13
Musculospiral in arm	12
Musculocutaneous in arm	7
Posterior and anterior interosseous	6 to 8
Sciatic	12
Internal popliteal	13
External popliteal	10
Anterior tibial	7
Musculocutaneous in leg	10

These figures, based on about one hundred and sixty cases of suture, are conservative; larger gaps may be overcome in selected cases.

11. What are the methods of overcoming nerve gaps?

Answer: (*a*) Elongation from moderate tension: usually two or three centimeters in a long nerve trunk.

(*b*) Flexion of joints: for the median and ulnar at wrist, this gives four or five centimeters; for the median and musculospiral at elbow, five to seven centimeters; for the sciatic, by flexing the knee, nine centimeters; posterior and anterior tibial, by flexing the knee, five to eight centimeters.

(*c*) Extension of joints: for ulnar, by extending the elbow, two centimeters; internal tibial, by adducting and extending the foot, three centimeters; sciatic, by hyperextending the hip, two centimeters.

(*d*) Position: cords of brachial plexus, by adducting arm and elevating the shoulder, five to seven centimeters; external cord, seven centimeters; brachial plexus, by rotating the head away from the affected side, one to two centimeters.

(*e*) Nerve transplantation: by transplanting ulnar to front of elbow, seven centimeters; by transplanting median from deep to subcutaneous position at elbow, seven centimeters.

12. What is the effect of nerve suture under tension?

Answer: After operation, the nerve rapidly fuses with the adjacent tissues near the area of suture. A nerve trunk exposed to tension, rapidly elongates so that the tension is relieved, or the suture line gives way. With very fine sutures limited to the nerve sheath a persistent harmful degree of tension cannot be maintained.

13. Should stay or relaxation sutures through the nerve substance be employed?

Answer: No; such sutures are harmful; first, by producing an undesirable degree of primary tension; second, by distorting the nerve bundles; third, by placing tracts of tissue reaction or degeneration in the path of regenerating neuraxes.

14. What suture material should be used in neurorrhaphy?

Answer: Only very fine silk (arterial to A silk, or 1500 to 2000 linen). Because of the much greater tissue reaction and leucocytic invasion produced by catgut, it should not be employed adjacent to growing neuraxes.

15. What bed should be selected for an operated nerve?

Answer: Preferably a normal intermuscular plane. If this is not available the nerve should be embedded in a muscle. The nerve should not be left against bone or skin; it should not be surrounded by any foreign or unvascularized substance.

16. How soon and how rapidly should the joint be extended after end-to-end suture of nerve made possible by flexing an adjacent joint?

Answer: A sutured nerve in an aseptic field is, within a few hours, supported and splinted by the adhesions of surrounding tissue. Beginning ten days after the operation, it is safe to start progressive extension of the joint, which may be increased two degrees on a measuring arc each day. Thus a ninety-degree flexion will be entirely overcome in forty-five days.

17. Does return occur much more slowly when large gaps have been overcome by suture and where the nerve has been elongated by progressive extension of flexed joints?

Answer: Our observations indicate that neuraxes penetrate about as rapidly and that regeneration occurs about as soon when large gaps have been overcome, as when small defects have been corrected by suture.

18. How should attached muscular rami be treated when a nerve trunk is implanted?

Answer: The rami should be preserved by splitting the nerve sheath, and freeing them from the main trunk as far as is necessary. If possible, they should be left to occupy the old nerve bed. They should not be divided, and should retain their function.

19. What is the proper point for a nerve section preparatory to suture?

Answer: The nerve should be resected back by a sharp razor to a point where a normal number of free fasciculi are exposed.

20. How soon should physiotherapy be started after operation?

Answer: As soon as the operative condition will permit; gentle massage and passive movement of the exposed parts should be used, if possible, on the third day. Progressive carefully graded electrical treatment without tension in the operative field may usually be commenced about one week after operation.

21. How often should the patient be examined for return of function after operation?

Answer: Every two weeks after neurolysis; every four weeks after suture or grafting, especially during the early months.

III. *Discharge.*—

22. When should a patient with peripheral nerve injury be considered fit for discharge from the army hospital?

Answer: (*a*) When deformity has been overcome.

(*b*) When sufficient sensation has returned to prevent burns or other injuries of the affected parts.

(*c*) When pain has been relieved.

(*d*) When sufficient motor power has returned to all the important muscles, so that progressive development will continue, without special treatment, under ordinary use.

THE REPUDIATION OF MATERIA MEDICA AND THERAPEUTICS IN MODERN MEDICAL TEACHING.*

By SPENCER L. DAWES, M.D.,
NEW YORK.

"FRIENDS, Romans, Countrymen, lend me your ears; I come to bury Cæsar, not to praise him."

It is pretty generally conceded that in no direction has such progress been made in the last two decades as in the study of medicine, and we are all happy that while once medicine was an art it has now become a science, more or less exact. So great has been the progress, so astounding have been the discoveries in our profession that when I set out to offer an extended criticism of medical teaching I am likely to be set down as a reactionary, to be dubbed unscientific and unprogressive.

Not only are the entrance requirements of most of the medical schools much more difficult to meet, securing thereby a better educated, and in that sense, a much more desirable type of student, but as well the teacher is better equipped and what he teaches is usually based upon carefully studied statistical data, case histories, hospital records, and laboratory findings, instead of long-winded didactic lectures expounding the individual opinions of the teacher. Every graduate is familiar with the use of the microscope, is supposed to be able to make an autopsy and give a comprehensive statement of the findings, can make a blood enamination and a Wassermann; has done spinal punctures and examined stomach contents; can differentiate in the laboratory between typhoid and paratyphoid; has an intimate acquaintance with calories, opsonins, and vitamines; can read a skiagraph if he can't take one; would no more let a patient get away without taking his blood pressure than his prototype of the early 40's would have parted from a case without using his lancet; by the use of his microscope he can readily differentiate between colitis and amebic dysentery; and these by no means complete the list of his accomplishments, each one and all of which were unknown to the average student of twenty years ago and all of which are necessary and desirable as well as being triumphs of research and study. So much for a very brief, incomplete, and really inadequate enumeration of the methods in the present day teaching of medicine.

In all this preamble you will note that not once have I mentioned anything in medical teaching that could in any way be connected with the cure of disease, the relief of pain, the assuaging of mental agony, not once have I breathed the words materia medica or therapeutics, and yet what is the excuse for the physician? Is it merely to be a scientific investigator, a diagnostician, a bateriologist, an histologist, a pathologist? Excepting only in surgery the cure of disease is not even a secondary matter, materia medica is not taught and therapeutics, with a few notable exceptions, is ignored.

No one has greater admiration for the achievements of his colleagues than I, nor is ready to give more unstinted praise for the outstanding marvels they have worked and are accomplishing every day in almost every branch of medicine, yet I cannot be blind to a grave and serious defect in modern medical educational methods, comprised in the practical abandonment of the teaching of materia medica and therapeutics in the medical schools.

The pendulum has swung far indeed from the day when a knowledge of drugs and the treatment of symptoms occupied first place in the curriculum; from the period of polypharmacy and "shotgun prescriptions"; so far that it may soon commence a backward movement to stop ultimately in a middle zone.

The first real assault of any magnitude upon materia medica and therapeutics was made when a little clique of medical politicians and osteopaths met in a certain doctor's office in the city of Albany, New York, and concluded a deal which made possible the passing of the Medical Practice Act of 1909.

This Act removed from the list of subjects in which a candidate must pass in order to practise medicine in the State of New York both materia medica and therapeutics, admitted to practice their calling several hundred osteopaths without examinations of any kind, and provided means by which graduates of schools of osteopathy might later be admitted to practice. The object of this outrageous deal was to get votes controlled by the osteopaths among members of the legislature. The effect can readily be seen if we make a careful examination of the announcements of what are called Class A medical schools on file in the library of the New York Academy of Medicine, which show that five of the smaller schools teach some kind of materia medica, fifteen teach pharmacology, and fifteen teach therapeutics. Not one of the larger schools teaches materia medica; the pharmacology taught consists for the most part in demonstrations of the physiologic action of types of therapeutic agents on animals, does not include the properties, doses, or methods of administration, incompatibilities, nor the preparations of drugs.

Only two of the larger and more important schools teach real, practical, applied therapeutics and in most of the fifteen it is not taught as a distinct branch but as a minor study accessory to something else. In one it is only electrotherapeutics, in another hydrotherapeutics, and in a third suggestive therapy—in other words the "Harvard idea" has cast a pall over all our medical schools and the "full time" teacher is rapidly pushing out the experienced clinician whose past efforts we have to thank for our present day progress, men to whom teaching was really a labor of love and never a mercenary pursuit. The heavy hand of the "little Iron Master" rests on

*Read at the twentieth annual meeting of the American Therapeutic Society, held at Atlantic City, N. J., June 7, 1919.

the colleges, for the recipients of his bounty must conform to his standards or lose their rating. Those who dominate today require of a graduate two very valuable requisites—he must be able to make a diagnosis and he must know pathology and be able to make an autopsy so that he can confirm the diagnosis. But treat disease, cure the sick, relieve pain and suffering—nonsense! What true scientist cares for such rot! Ask a medical student what he is particularly interested in—he will tell you of any one of many different, very laudable things excepting the cure of disease. It is perfectly safe to assume that, no matter how ridiculous such an attitude may appear to the modern teacher of medicine, the average man when he goes to a doctor cares not a "tinker's dam" about the predominance of giant cells over phagocytes, of the disproportion of osteoblasts, of whether the autopsy findings in his case will reveal that he had a large white kidney instead of a small red one, however desirable it may be to know these facts, but goes for the specific purpose of being cured or relieved from his distress either real of imagined.

One of the most skillful and best known physicians in this country told me recently, apropos of the abandonment of therapeutics, that the only instruction in that subject given in the college in which he is a dominating factor is covered by five or at the most ten minutes at the end of an hour or two lecture on some given disease.

One of the leading men in one of our greatest medical schools once complimented me on my qualities as a teacher and ended by saying "but your subject should never be taught." A week later I was called to see his wife who was ill with bronchitis; my medical friend remarked that he couldn't control the cough having given paregoric, brown mixture, heroin, codeine, creosote, muriate of ammonia, and several other drugs in the preceding twenty-four hours without avail! He certainly practised what he preached.

Recently I saw a man in consultation and made a diagnosis of amebic dysentery on laboratory findings. He received inadequate treatment and then went to a man who is considered by many the best medical man in this country. He was placed in a private hospital and during six weeks was examined by twenty-four different specialists, including dentists, radiographers, psychologists, oculists, and aurists and at the end of that time, when he rebelled and was about to leave, he was treated with emetine and speedily cured.

If a man knows no materia medica what might happen if he was prescribing large doses of iodide of potassium and at the same time decided to give his patient calomel; would he distinguish between tincture of opium and the camphorated tincture of the same drug; might he not give the same doses of the U. S. P. and Pearson's solution of the arsenate of sodium; will he give his patient tincture of the chloride of iron and let him drink tea immediately thereafter? A wonderfully made chronometer watch, taking a long time and many dollars to construct, may have in it a strong main spring, a perfectly adjusted hair spring, and all the bearings may be jeweled—it may even have a luminous dial, but if it is not provided with hands it cannot perform the only duty for which a watch is made. And so, to pursue the analogy, a doctor may be a skillful diagnostician, an experienced pathologist, a wonderful microscopist; he may be experienced in the use of all instruments of precision, and yet if he knows nothing of materia medica and of therapeutics he cannot perform the only duty for which his calling is an excuse.

Is it any wonder that so many practitioners have listened to the siren song of the detail man who brings a generous line of samples, small bottles for the patients and large ones to try on his wife, together with literature (Heaven save the mark!) describing its virtues and its physiologic (?) action; that he gives fever tablets, kidney pills, coryza tablets, heart tonics, hepatic stimulants, and anti-this and anti-that nostrums?

Do you wonder that the general public, in its desire to have something done for its ills, crowds the waiting rooms of the osteopath, the chiropractor, and the X scientists, or turns to some of the so-called religious newspapers to read with interest the testimonials of ex-statesmen, ex-doctors, ex-public officials, and clerical incompetents as to the value of some patented article the very name of which shows its unscientific origin and composition?

Room 703, Hall of Records.

Medicolegal Notes.

Agreement Not to Practise After Sale of Business.—In an action in equity to enjoin the defendant from pursuing the practice of medicine and surgery in a specified county in Iowa, the Iowa Supreme Court holds that an agreement that, in consideration of $1,000, the defendant would relinquish his business to the plaintiff and retire from practice for a period of ten years, was not unreasonable and oppressive in its restrictions, either as to time or area. The court said that it is not an unheard-of or very unusual thing for a well-established physician of good repute to enjoy a practice co-extensive with his county, and even a young physician, whose present practice is comparatively limited, both in the number of his patients and in the area in which he finds his patrons, may yet reasonably hope, if well qualified, to extend his practice much beyond the immediate vicinity of his office or home. The agreement was valid, although there was no transfer of tangible property, such as an office, instruments, or supplies. A supplemental agreement for a nominal partnership, because of the fact that another physician had located in the city, was held not an unlawful conspiracy in restraint of trade; there being no undertaking to interfere with such other physician.—Rowe v. Toom, Iowa Supreme Court, 169 N. W. 38.

Establishment of County Hospitals.—The Indiana Supreme Court holds that a board of county commissioners, after having ordered the establishment of a county hospital, and provided for the levying of a tax for the expenses thereof, upon the filing of a petition therefor under Burns' Ann. St. 1914, §3776a, providing that the commissioners upon proper petition "may" enter such order, may rescind the order provided no contractual rights have been created. The statute, in view of the word "may" makes the establishment of a hospital discretionary with the commissioners and leaves the action of the board open to review on its part.—State v. Elliott (Ind.), 121 N. E. 82.

"Disposing of" Drugs.—It is held that a statute (Delaware Rev. Code 1915, § 3595), declaring it an offense to sell or in any way "dispose of" morphine, etc., includes furnishing without sale, State v. Handy (Del.), 105 Atl. 426; and also that one who has a compound of morphine in his possession and permits another, not being a licensed physician, or without the authority of a certificate of a duly licensed physician, to have or use it, unlawfully disposes of it in contravention of the statute.—State v. Rothman (Del.), 105 Atl. 427.

EFFORT SYNDROME AND EPINEPHRIN.

THE physically unfit, those apparently without organic lesion, but weaklings, and unable to keep up with their fellow men, have been known, not only to physicians but to the world at large for a long time. They were recognized at the time of the Civil War, and considered unfit for military duty. During the recent struggle they appeared in large numbers, presenting certain irregularities of the cardiac rhythm as the most striking symptom. Classified at first as "D. A. H." by the British, the term "effort syndrome" was soon introduced and generally used, for it was found that the cardiac irregularity was merely one of the symptoms by which the condition was evidenced. These individuals function at a low stage of efficiency, often during the greater portion of their lives, and it has been pointed out that they are frequently told in their childhood that they have weak hearts and must restrict their activities. As soldiers they are a constant source of trouble and annoyance, for they are unable to sustain any mental or physical strain, and have to be helped along.

In the course of an investigation of some of these patients it has been found that about 60 per cent. of them show an exaggerated reaction to the intramuscular injection of epinephrin. This reaction consists of increase in the pulse rate and of the blood pressure and certain signs and symptoms, such as tremor, pulsation, nervousness, precordial pain, dizziness, or restlessness (J. T. Wearn and C. C. Sturgis, *Archives of Internal Medicine*, 1919, xxiv, 247). But the other 40 per cent. showed no such reaction, and clinically there was no way to differentiate between the two groups. It had already been suggested that the effort syndrome might be associated with some form of dysthyroidism, but a study of the basal metabolism failed to support such an hypothesis. These investigators showed, however (*ibid*, p. 269), that following the injection of epinephrin there was a definite increase in metabolism in those cases that showed a positive epinephrin reaction. They suggest that the difference may be due to some change in the sympathetic autonomic nervous system. Clough showed (*ibid*, p. 284) that there was no evidence of cardiac trouble as demonstrated by the electrocardiograph in these "positive" cases, and it seems necessary to fall back upon the theory that they are examples of faulty functioning of the endocrine glands. The fact that Smith (*ibid*, p. 321) was able to bring about an improvement in the condition of these patients by very carefully graded exercises is not necessarily against such an explanation.

The great difficulty is that at the present time our means of recognizing defects in the workings of these glands are so faulty that it is almost impossible to obtain any positive evidence. One of the most crying needs of present-day medicine is a careful, and above all a sane, study of these all-important glands with a critical review of a literature that is full of inconsistencies and the development of some satisfactory method of determining what gland or glands are at fault. That once accomplished, the whole vast group of neurasthenias, psychasthenias, neuroses, etc., would vanish almost into nothingness.

MALARIA IN GREAT BRITAIN.

AS one of the consequences of the war, malaria has reappeared in the British Isles during the past few years. Many soldiers served in countries notoriously malarious, notable in Macedonia, and some who were invalided have had the malaria parasites in their blood. Also a certain number of infected mosquitos were probably transported into Great Britain. A series of reports and papers dealing with malaria have been issued recently by the English Local Government Board, which show that there is a progressive decrease in malaria contracted in England. It is estimated that 231 cases were contracted in 1917 and 99 in 1918. The decrease of cases in 1918 is believed to be due to the more complete arrangements for investigation and control which were made. On account of the cessation of hostilities, however, it is likely that the total number of malaria carriers transferred to England during the present year will be greater than in any year of the war. It is unavoidably the case that many British soldiers are being demobilized who have been infected recently with the malaria parasites, and that many of these after demobilization continue to get relapses at frequent intervals. Instead of being concentrated under medical supervision in mosquito-proof huts in a limited number of military areas these soldiers will be scattered throughout the country each in his own home. If these homes are so situated and are of such a character that they offer breeding places to anophelines, constant watchfulness, and, when necessary, prompt action will be required to prevent the occurrence of new cases among them.

Lieut.-Colonel James, R. A. M. C., who has recently made a report on the risks of the spread of malaria in relation to demobilization, points out that the factor which determines the spread of the disease is neither the number of anopheline mosquitos in the district, nor the number of human malaria carriers. It depends rather upon the close

and continuous association between the malaria carrier, the anopheline, and the susceptible person. This is apt to occur only in the type of dwelling which the mosquito selects as its permanent feeding and resting place. It has been shown that the malaria-bearing mosquito does not stay in a well lighted house or modern hospital. Clean, bare walls and ceilings, large windows, and little furniture do not attract it. On the contrary, it selects cottages or old-fashioned houses, where the rooms are "stuffy" and hot, ill-lighted, ill-ventilated, with dark recesses, cupboards, old curtains, and much furniture. In such a place the mosquito is altogether at home, and if there is restricted living or sleeping accommodation, infection is very likely to be carried from the malaria carrier to the susceptible person.

In Great Britain the malaria problem will probably never again be serious, but in parts of the United States it is a grave problem and is responsible, directly and indirectly, for an immense amount of mortality and sickness. The conclusions drawn by Colonel James are suggestive and worthy of consideration.

MORTALITY AMONG LUNATICS.

A LESSON taught and emphasized by the war has been that diet has much to do with the maintenance of good health. In particular this fact has been driven home in the case of lunatics. The fifth report of the British Lunacy and Mental Deficiency Board of Control provides an apt illustration of the need for feeding lunatics upon an adequate, nourishing, and well balanced diet. The mortality of the British insane during the war was appalling. The report shows that the yearly average death rate among the certified insane in British asylums during the years 1918 and 1919 was 208 per 1,000. The report seems to demonstrate that the terrible mortality was largely due to the lack of food or, perhaps, rather to its unscientific adjustment for sick people. It is true that sufficient calories were supplied to keep the patients in a satisfactory state of health, that is, from the theoretical standpoint, but those responsible for the rationing of the patients appear to have omitted from their calculations due consideration of the accessory food products, the vitamines, present to a large extent in milk and fat, elements which were deficient in the dietary. It must be also taken into consideration that the supply of fuel was limited during the winter months. Thus, without a compensatory increase in the quantity or nutritive quality of the food, and without warmer clothing by day and night, the vitality of those suffering from mental diseases was necessarily lessened, and they became highly susceptible to tuberculosis, diarrhea, and dysentery, showing a lowering of the vital powers of the body.

Another lesson to be learned from this high mortality among lunatics is that a well balanced, an adequate, and a nutritious diet is an important factor in successful treatment. A spare diet or one lacking in any of the elements which go to make up a practically and scientifically satisfying diet is not adapted for lunatics, which means that the insane must be well fed, and the war appears to have shown that if economy in this respect has to be practised, the rationing of patients in institutions for the insane should be left in the hands of those who have made a study of mental diseases and that too great reliance should not be placed on a diet the value of which is based on its caloric value only.

PERSONAL IDENTIFICATION BY THE SKELETON.

THE late distinguished forensic expert, Lecha-Marzo, published just before his death a little work on this subject (Castellanos in *Vida Nueva* for August), which deals especially with the case of a collector of rents who had vanished with a shortage of 15,000 pesetas. This was in 1877 and after the expiration of forty years the remains of a skeleton brought to light were thought to belong to the missing man. The court invoked hastily pronounced identification impossible, but the matter was subsequently put up to Lecha-Marzo. The latter was requested to reply to certain queries: Were the remains those of Jiménez, the missing rent collector; and did death come to him in a violent form? The expert first decided that the skeleton was that of a male as a result of study directed to the pelvis, lumbar vertebræ, and ribs; next he fixed the age as that of an individual not over 30 years and more than 20. This was determined wholly by skeletal development with special reference to consolidation of certain sutures and epiphyses. The first experts gave the age as 30-35, but Lecha-Marzo in his turn proved that it was close to 30 which was the age of Jiménez. The height was determined by the method of Rollet as 1.769 meters, which coincided with the height of Jiménez. The character of the bones showed them to belong to a man with large extremities and poorly developed thorax, which agreed with the habitus phthisicus and with the constitution of the missing man. The lower jaw with its dentition was a valuable means of identification, since the teeth showed caries of the third degree and a missing third molar which had been extracted. There were no fillings to serve for identification. In regard to the mode of death the only evidence which could have been adduced dealt with a possible cranial fracture. Of this there was at least suspicion but one would have to discount the blows of implements made in unearthing the remains.

A NEW FAMILIAL SYNDROME.

FIGUEIRA has recently described a new familial affection which must not be confounded with another which is not familial, but which may also be termed "Figueira's disease," should it prove to be well sustained. The older affection was described by him as a minimal and benign form of infantile paralysis affecting the neck musculature, and was mentioned in the MEDICAL RECORD at the time. There is a question as to whether the case reported by him could not as well or better have been an

example of post-diphtheritic paralysis. The more recently described condition as found in the *Brazil-Medico* for July 19, is a form of infantilism as seen in two brothers whose stature was very low—75 and 108 cm. respectively, in place of the average for the age of 108 and 135 cm. There was, in addition, a certain grade of mental debility and some deformities, chiefly of the osseous system. The epiphyses were overdeveloped, and some of the movements of the arm were crippled as a result. In some of the muscular groups there was rigidity which suggested the pseudotetany of Escherich. Endocrine and luetic pathology could not explain these cases. A committee was appointed to study them and report as to the precise nature.

Sympathetic Ophthalmia.

Much has been written of late concerning the relative infrequency of this condition, and especially the war has shown how small a percentage of those wounded in the eye really develop it. In a collective abstract in the *Journal de médecine et de chirurgie pratiques* for August 25, we find that nearly one mobilized man in 1,000 lost an eye. Nevertheless, the percentage of sympathetic ophthalmia was very small. The symptoms of the latter are usually given as photophobia, lacrymation, blepharospasm, contraction of the visual field, sluggish pupil, opacities of the vitreous, etc. So experienced an ophthalmologist as Morax has seen but 39 cases, the great majority of which began in the first three months after injury. However, it is known that exceptionally the affection may develop very late, even several years after the traumatism. Of the 39 cases 21 recovered, 13 were blinded, and 5 were left with visual acuity of 0.3 to 0.4. Favorable results gave an acuity of 0.5 to 1. To be effective enucleation must be performed within a fortnight after infection of the wounded eye.

News of the Week.

Red Cross Prepares for Emergencies.—According to a recent announcement, the Atlantic Division of the American Red Cross has perfected plans to put its forces into operation quickly in the event of any great disaster in its territory. To this end it is collecting large quantities of hospital supplies, tents, cots, blankets, etc., for storage at convenient places. The Motor Corps organizations are being retained in such a way as to make them speedily available. Men formerly in the service voluntarily have identified themselves as campaign workers in most chapters.

New Organization to Combat Legislation Inimical to Medical Practitioner.—A letter has been sent to all members of the New York County Medical Society and to other members of the profession in New York City, over the signature of Dr. John P. Davin, setting forth the negative value of the efforts made by existing medical organizations and individuals in combating the enactment of unjust and injurious measures and laws limiting and harassing the legitimate practice of medicine. The letter suggests the organization, under the name of "The New York Medical Association," of a body of medical men who, instead of sporadically opposing laws unjustly affecting the practice of medicine, shall combat them unceasingly. By means of such an organization it is expected to obtain from legislative bodies the same respect for the practitioners of medicine which is now accorded as a political right to every form of organized labor and industry. The aims of the new organization, briefly stated, are to insure as far as possible the professional and material welfare of its members now threatened by professional politicians from without, and by medical politicians from within. It asks the enrollment among its members of every physician who can subscribe to these principles.

New Jersey Reports Low Death Rate.—The vital statistics for the State of New Jersey during the month of August have just been made public and show a death rate of 10.38 per cent. There were only nine deaths from typhoid fever during the month. The diseases which showed the highest mortality were pulmonary tuberculosis, diseases of the circulatory system, diseases of the nervous system, Brights disease, and infantile diarrhea.

An Important Provision of the War Risk Insurance Act.—The Bureau of War Risk Insurance calls attention to the importance of one of the provisions of the War Risk Insurance Act upon the fulfillment of which may depend the validity of a claim to compensation under the Act. This provision is as follows: "No compensation shall be payable for death or disability which does not occur prior to or within one year after discharge or resignation from the service, except that where a medical examination made pursuant to regulations, at the time of discharge or resignation from the service, or within such reasonable time thereafter, not exceeding one year, as may be allowed by regulations, a certificate has been obtained from the director to the effect that the injured person at the time of his discharge or resignation was suffering from injury likely to result in death or disability." Request for the certificate mentioned in this provision should be made to the Chief Medical Advisor, Bureau of War Risk Insurance, Washington, D. C.

Addition to Hospital.—Plans have been made for the enlargement of the Kosher Hospital, Brooklyn, N. Y. The addition to the present building will give the institution 150 beds.

Vital Statistics for New York State.—The Vital Statistics Bulletin of the New York State Department of Health for October, shows that during the months of June, July, and August, of this year, the general death rate of the State has been the lowest ever recorded, being 10.8 per 1,000 population for June, 10.7 for July, and 10.4 for August, which is 10 per cent. lower than it was during the same months of 1918, and 20 per cent. lower than for the same months of 1913-1917. The rate for New York City for these same months was 9.9 in both June and July, and only 9.2 in August, which are also less than for the same months in 1918 and in the preceding five years. During the first eight months of 1919, the number of deaths from typhoid fever were one-third less in number than during the first eight months of 1918. During this same period the number of deaths from measles and whooping cough both declined 80 per cent. The number of deaths from pneumonia was almost the

same for the first eight months of both years. Influenza continued to show an extreme prevalence as compared with the first eight months of last year, there being an excess of 6,821 deaths from this cause.

Eight-Hour Day for Nurses.—The Presbyterian Hospital, New York, announces that it has adopted an eight-hour day for student nurses. The new schedule provides a fifty-six hour week for night and a fifty-two hour week for day duty. Heretofore nurses on the day shift have been on duty nine and one-half hours and those on night duty eleven hours. The management believes that the shorter hours will bring more efficient service and improve the health of the nurses.

Increase of Drunkenness in Connecticut.—Statistics announced by the Hartford police court officials for the month of September show a heavy increase for drunkenness cases, there having been 177 persons arraigned on that charge during September, as against 71 in August and 60 in July. The vast majority of these cases resulted from wood alcohol preparation, although cologne, Jamaica ginger, and horse liniment have figured in some of the hearings.

Charitable Bequests.—Under the will of Solomon Schinasi gifts of $300,000 each are made to the Woman's Hospital, Lying-in Hospital, St. Luke's, Sydenham, Presbyterian and Children's Hospitals, and four others to be selected by the son of the testator. The will also provides for the establishment of a Solomon Schinasi Memorial Hospital.

By the will of the late Elizabeth Burk of Philadelphia the sum of $500 is bequeathed to the Kensington Dispensary for Tuberculosis.

By the will of the late Kate E. Nessly of Philadelphia the sum of $500 is bequeathed to the East Liverpool Hospital of East Liverpool, O.

By the will of the late Rachel P. Arnold of Philadelphia the sum of $1,000 is bequeathed to the Mt. Sinai Hospital.

By the will of the late John Moss, Jr., of Philadelphia the sum of $1,000 is bequeathed to the Pennsylvania Hospital, and the residue of his estate in equal shares to the Jewish Maternity Hospital, the Jewish Seaside Home at Atlantic City, N. J., and the National Farm School at Doylestown, Pa.

By the will of the late Louise M. Pepper of Philadelphia the sum of $1,000 is bequeathed to the Methodist Hospital.

By the will of the late Charlotte Rattery of Philadelphia the residue of her estate is to revert to the Episcopal, Frankford, Samaritan and St. Mary's Hospitals, the Protestant Episcopal City Mission and the Society for the Protection of Children from Cruelty.

Dr. Caroline S. Finley of New York City, director of Unit No. 1 of the Women's Overseas Hospitals, has returned to this country.

Dr. Charles Gluck has returned from service in the army and has resumed his practice at 955 West End Avenue, New York City.

Dr. Richard P. Strong of Harvard University has sailed for Europe to take the position of general medical director of the League of Red Cross Societies, with headquarters at Geneva.

Dr. Marie Louise Lafort, director of Unit No. 3 of the Women's Overseas Hospitals, who has been in this country for a few weeks, has returned to France to take charge of the American Memorial Hospital which the American Fund for French Wounded is establishing at Rhiems.

Obituary Notes.—Dr. Charles J. Langlois, a graduate of the College of Physicians and Surgeons, Baltimore, in 1910, died suddenly from heart trouble at his home in Pittsfield, Mass., on October 1, aged 31 years.

Dr. Cornelius Van Riper, a graduate of the College of Physicians and Surgeons, New York, in 1866, for forty years a practitioner of medicine in Passaic, N. J., died after a long illness at his home in Pasadena, Cal., on October 9, aged 79 years.

Dr. Jacob Dennis Arnold, a graduate of Washington University, Baltimore, in 1876, died from carcinoma of the pancreas at his home in San Francisco, on September 26, aged 63 years. He was lecturer on throat and ear diseases at the College of Physicians and Surgeons, Baltimore in 1884 and 1885, and president and professor of diseases of the throat and ear in the San Francisco Polyclinic from 1887 to 1889.

Dr. George Gilmore Weld died at his home in Old Town, Me., on September 28, aged 64 years. He was a graduate of Dartmouth Medical College, in 1884, an ex-mayor of Old Town, and a member of the Maine Senate in 1910 and 1911.

Dr. Thomas J. McCoy, a widely known eye, ear, nose, and throat specialist of Southern California, died at his home in Los Angeles, on September 30, aged 62 years. He was a graduate of the Kentucky School of Medicine, in 1880.

Dr. William Gaynor States died at his home in New York City, after a long illness, on October 6, aged 58 years. He was a graduate of New York University Medical College, in 1881, and was adjunct professor in dermatology at the Polyclinic Hospital in 1917 and 1918. Dr. States was a member of the American Medical Association, the New York Academy of Medicine, and the Medical Society of the County of New York. He translated a number of French and German medical books into English.

Dr. Howard Kennedy Hill of Philadelphia, died at the Presbyterian Hospital on September 11, at the age of 40 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1903. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania and of the American Medical Association.

Dr. Emanuel S. Gans died of pneumonia at Philadelphia, on September 30, at the age of 63 years. He was graduated from Jefferson Medical College in the class of 1886 and from the Medico-Chirurgical College in the class of 1911. He was for several years lecturer on dermatology in the Medico-Chirurgical College and dermatologist to the Medico-Chirurgical Hospital, the Philadelphia General Hospital and the Mount Sinai Hospital. He was a member of the Philadelphia Dermatological Society.

Dr. Mahlon B. Dill died at Perkasie, Pa., recently of apoplexy at the age of 67 years. He was graduated from Jefferson Medical College in the class of 1881. He was a member of the Bucks County Medical Society.

Correspondence.

CORRECTION OF ERRONEOUS STATEMENTS IN THE CHICAGO DAILY TRIBUNE.

To the Editor of the Medical Record:

Sir:—In the *"How to Keep Well"* section of the Chicago *Tribune* for October 6, 1919, there appeared an article carrying the caption "Would avert 'Flu' attacks." This article is in some respects so misleading and reflects so seriously on the U. S. Public Health Service that I would request you to give this letter space in your columns.

The portions referred to read as follows (Italics are mine):

There is considerable diversity of opinion as to whether vaccines need to be made from the local strains of bacteria. Since very few communities can get vaccines from local strains, they will have to use the standard strains or do without.

Some State boards of health will furnish vaccines as they did last winter.

The question about lipovaccines is a difficult one to answer. The Public Health Service has refused to allow the commercial houses to sell lipovaccines. *Some city and some State health departments will doubtless manufacture them and distribute them to their citizens. The citizens who live in such communities are lucky. It looks as though other citizens will have to go without. The army is supplying lipovaccines for the soldiers. They offer it to employees of the War Department. They have issued two favorable reports on lipovaccines as protective agents against pneumonia, one based upon thousands of vaccinations done at Camp Upton, and the other upon thousands of vaccinations done at Camp Wheeler. Not only are they behind it with their reports, but they are supplying it for the use of those for whose health they are responsible.*

In civil life vaccination must be done at one sitting, or it will not be done at all. The people will not come three times at week intervals for injection. Therefore vaccination to be done at three sittings is not practicable. *A great many people want to be vaccinated with lipovaccine. The commercial houses are willing and able to supply them with the vaccine The Public Health Service will not let them.*

The physicians who are dependent upon the commercial houses for their supplies will have to get along without lipovaccines. They can get the three-injection vaccine. Some health departments will equip their physicians with the other kind.

The first statement objected to as inaccurate is the reference to the use of lipovaccines in the Army, the statement reading "The Army is supplying lipovaccines for the soldiers." The fact is that the Army discontinued distributing lipovaccine some months ago and withdrew that which was outstanding.

It is also stated that the Army issued a favorable report on lipovaccines "based on thousands of vaccinations done at Camp Upton"; this is incorrect. The fact is, as may be ascertained by a glance at the Camp Upton report (*Jrnl. of Exp. Med.*, July, 1918, p. 21, Cecil and Austin) that a saline suspension vaccine was used. The reference to lipovaccine at Camp Wheeler is correct, in so far as the preparation used is concerned.

The chief objection raised is to the coupling of the refusal of the U. S. Public Health Service to license lipovaccines with statements which imply that for this reason people are being deprived of a valuable prophylactic agent. The facts are that the U. S. Public Health Service has been and is conducting extensive clinical and experimental investigations of lipovaccines and is of the opinion that they are not now on a footing which makes them desirable for general use.

The lack at present of satisfactory potency and sterility tests for lipovaccines has led the Bureau to decline to license such vaccines for interstate sale, and the evidence at our disposal indicates that a saline vaccine containing pneumococci is at least as effective as an oil suspension of the organisms.

The U. S. Public Health Service has always made it a rule to license only such biologic products as are safe for general use and within recent years has added the restriction that for original license satisfactory evidence of efficiency must be presented as well, if it is possible to secure such evidence.

Constructive and reasonable criticism is welcomed, but such an insinuation of failure of the Service to perform its duties as is carried in the article referred to is unwarranted and unjust.

Rupert Blue,
Surgeon General, U. S. P. H. S.

Washington, D. C.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, Sept. 12, 1919.

Vaccination in Great Britain.—It is a concise commentary on the lack of thought among the masses of this country and of the tendency of politicians to bow to the vox populi even though it be in direct opposition to the teachings of science and experience, in other words, vox Dei, that vaccination appears to have fallen into disrepute and disuse. And this in the land in which the method of immunizing against smallpox was discovered and in which it wrought so much good. It is true that people of the present day do not recollect the ravages made by the disease in the early part of the last century, although there are yet living some who can recall the pitting that was so commonly seen in England. No lesson has been learned from the fact that smallpox was practically eliminated by vaccination, and it may need an epidemic throughout the country to drive the lesson home once more. In any event, owing to the relaxation of the regulations as to vaccination, presumably due to the desire to cater to the ignorant and popular view of the question, vaccination is largely a dead letter. British troops have been serving in countries in which smallpox exists and it is possible that some of those who have contracted the disease may infect members of the civil population, despite the steps taken at the seaports to prevent its spread. Among an unvaccinated people an epidemic of smallpox would doubtless spread like wildfire and it is within the bounds of possibility that in this respect we may revert to the conditions of one hundred and fifty years ago. Opponents of vaccination are generally inconsistent. They argue that vaccination is not only useless but dangerous and many of them almost in the same breath allow that it confers immunity or partial immunity and still declare that it is soon enough to vaccinate children when the malady has broken out. Perhaps nothing but a scourge of smallpox will convince such persons that vaccination is a matter of national necessity.

The Medical Situation at the Northwest Frontier of India.—Very severe strictures have been passed in the lay papers on what was termed the mismanagement of medical matters during the recent campaign against Afghanistan. It was claimed in one journal that the campaign from the medical aspects approximated in its defective arrangements that of the first Mesopotamian and that there was a complete medical breakdown. The official reply to the criticisms aimed against the medical organization is contained in a White Paper issued a short time ago and practically denies that a breakdown occurred. However, as generally happens in such cases, the official reply has not been accepted in toto and criticisms continue to be levelled against the manner in which the medical department of the army fighting on the Afghanistan border was conducted. It appears to have been proven without doubt that polluted or rather infected water, was at the root of all the trouble and that in consequence severe cholera epidemics broke out. Lieut. General Sir C. H. Burtchaell, Director General of Medical Services in India has afforded Reuter's correspondent at Simla the fullest opportunity to examine all papers connected with the medical statistics of the sickness of troops on the Afghanistan frontier. From a perusal of these it is gathered that an unusually severe cholera epidemic occurred at no fewer than thirty stations. There were 76 cases with 30 deaths among the British troops, and 2,045 cases and 617 deaths among the Indians, or 30 per cent. fatal cases. According to those who criticise the medical arrangements, this widespread and fatal outbreak was due to a defective or it should be said inadequate water supply. It is stated that in one place Kohat, only two tanks existed, obviously insufficient for the many units collected there. Therefore, the troops and followers had to drink from the small irrigation channels which being open were easily fouled and hence the cholera epidemic. On the other hand, the Director General attributes the outbreak to the difficulty in bringing the undisciplined camel and mule transport-drivers under control. No methods prevented them from drinking polluted water. In the Far East and especially in an out of the way country, as the North West frontier of India, the army medical department is necessarily subjected to the severest tests, and those living under strictly civilized conditions are very apt to underestimate the difficulties met with. The bright side of the situation was, that in face of all the impediments encountered, the manner in which cholera was suppressed has been a triumph to medical skill and devotion to duty. One hundred thousand men were inoculated within two weeks. It is also worthy of comment and a tribute to the principles of vaccination, that inoculation against cholera should have once more proven its value on a large scale. The opponents of vaccination against smallpox might read in this an instructive object lesson.

Increase in the Death Rate of Lunatics.—The fifth annual report of the Lunacy and Mental Deficiency Board of Control for 1918 which has just been issued as a White Book shows that there was a considerable increase in the death rate among lunatics during 1918. An increase of 3.7 per cent. in the case of male and of 2.4 in the case of female lunatics was observed during that period. The steady increase caused the board to refer the matter for inquiry to three Commissioners who after an investigation, attribute part of the increase to the effect of war conditions, such as reduced supply of food, inadequate staffs, and some degree of overcrowding, all of which are of a temporary character, and already show some improvement. The Commissioners, however, are definitely of the opinion that war conditions alone do not account for the alarming increase of sickness, and that their disappearance will not eradicate the communicable tuberculosis, dysentery and enteric, which have obtained so strong a hold on a number of asylums. They have drawn attention to several questions pertaining to asylum practice and administration, which in their opinion have materially added to the gravity of the situation and which call for special effort toward improvement. On the other hand, a further decrease is reported in the number of notified insane persons under care in England and Wales, the figure on January 1, 1919 being 116,703 or 9,138 fewer than twelve months previously. In the three preceding years there had been decreases of 3,278, 3,159 and 8,188 respectively, as compared with an annual average increase of 2,251 for the ten years ending on December 31, 1914. The relative percentages of the sexes under care, males 42.8, females 57.2, show a continued reduction in the proportion of males. The private patients under care on January 1, 1919, numbered 12,320 an increase of 1,530, or 14.2 per cent. The total expenditure on the upkeep of the county and borough asylums in England and Wales amounted to $20,313,760. The average weekly cost of maintaining the patients in the county and borough asylums for the year ending March 31, 1918, excluding the cost of repairs, additions and alterations was $12.55 in county and $3.15 in borough asylums. It is stated in the report that the present accommodation in certified institutions for mental defectives, in which there were 6,577 patients at the end of the year, is insufficient to meet the requirements of the act.

It may be said that while the report seems satisfactory with regard to the decrease of lunacy in England it really is not so satisfactory as at first sight it appears to be. If the statistics be looked into carefully it will be observed that the main reason for the smaller number of lunatics is the substantial increase in mortality. As a matter of fact the number of admissions has been higher in most of the classes, but this has been more than equalized by the great number of deaths. As will be noticed in the résumè of the report given above the Commissioners attribute to a large extent, the high death rate to the reduction in quantity and deterioration in quality of the food supplied to the patients. Possibly too great attention has been paid to scientific feeding with a view to economy. If the diet has not been of a sufficiently nourishing nature, it will account for the increased susceptibility shown to the communicable diseases, tuberculosis, dysentery, and typhoid fever.

Plague in London Docks.—The Ministry of Health has announced with regard to the notice issued on August 30, as to a case clinically diagnosed as plague in a member of the crew of the steamship Clan Lamont, that a report has now been received from the bacteriologist stating that further investigation has resulted in the discovery of evidence confirming the original diagnosis of plague.

Obituary.—Dr. Charles Arthur Mercier, the well known neurologist and criminologist passed away at Bournemouth, on September 3, somewhat suddenly, although he had been an invalid for many years. Original articles and communications from the pen of Dr. Mercier have been published in quite recent numbers of the Medical Press. The deceased psychiatrist and neurologist was of Huguenot extraction and had a brilliant career as a medical student. He practised as an alienist and was for the greater part of his life resident physician at a private asylum. Mercier tried with increasing zeal to pass a bill through Parliament to legalize the treatment of insanity in its early stages. It was as a writer, however, that Mercier shows at his brightest. He was almost a purist in the use of the English language and wrote several books on his own subject. His "Text Book on Insanity" which was brought out in 1902, was one of the first, if not the first, comprehensive discussion of insanity from the practical standpoint. He was awarded the Swiney Prize on two occasions. Mercier was a good speaker but perhaps both in his speeches and writings rather too prone to argument. He visited America more than once and was well known in medical and literary circles there. On the whole, the verdict of posterity will probably be that Mercier was one of the most talented medical men who ever lived.

Dr. Alexander Macalister, professor of anatomy at the University of Cambridge, died at Cambridge on September 2, after a long and trying illness. Some months ago he underwent a severe operation in Dublin, and after his return to Cambridge never afterward left his house. Professor Macalister was born in Dublin in 1844 and educated at Trinity College, Dublin. In 1877 he became professor of anatomy and chirurgery at Dublin and in 1883 succeeded the late Professor Sir George Humphrey in the professorship of anatomy in Cambridge University. Dr. Macalister was a man of wide culture, the author of numerous memoirs and text-books for students in zoology and physiology a well known Egyptologist and an extensive traveler especially in the East. The writer of this letter has just been chatting with a distinguished Fellow of Caine's College, Cambridge, and an old friend of the late Professor Macalister. He gives testimony to the charming personality and kind disposition of the deceased professor.

A Function of the Internal Secretion of the Thymus.—Muller found that exhausted muscles in experiment animals—frogs, rabbits, etc., were restored to vigor by thymus injections. As between the muscle and its supplying nerve it was evident that the stimulant effect was upon the latter. We already knew that in animals extirpation of the thymus causes myasthenia. —*Le Progrès Médical.*

1. "The Jest": The Destruction Wrought by Hate. Smith Ely Jelliffe and Louise Brink.
2. Pneumonia and Empyema at Camp Div. Simon S. Leopold.
3. Multiple Neuritis of Toxic Infectious Origin. Alfred Gordon.

3. Multiple Neuritis of Toxic Infectious Origin.—Alfred Gordon summarizes the histories of seventeen cases of polyneuritis following infectious diseases and six in which there was apparently a causal relationship between diabetes and polyneuritis. The special features of acute febrile polyneuritis are found in the rapidity of development and improvement of the symptoms, in the bilateral paralysis of the seventh nerve, in paralysis of the ninth nerve, in the involvement of the sphincters, finally in the existence of slight subjective and objective sensory disturbances. Of the seventeen cases of polyneuritis which followed infectious diseases three were in pneumonia, five in typhoid fever, two in measles, two in influenza, and three in puerperal states. In the pneumonia and typhoid cases there were distinct evidences of hepatic disorder with enlargement of the liver. The question naturally arose as to whether the original infectious elements, the hepatic lesion, or both, were etiological factors in the process of invasion of the peripheral nerve trunks. The uniformity of the morbid neuritic manifestations was so striking in these cases that the same question presented itself in the remaining nine cases, although no enlargement of the liver was in evidence in them. In the latter group there was a history of periodical urobilinuria, occasional yellowish tint of the cutaneous surface and conjunctivæ, with generalized pruritus, gastrointestinal manifestations and tenderness in the hepatic region, all denoting disturbances of the function of the liver or of the portal circulation. While the symptomatology, in the writer's cases, was mildly pronounced, the morbid process extended rapidly from the lower to the upper limbs. Commencing in the fingers, the paralysis spread over the arm. In one case, in addition to the paralysis of the limbs, there was also bilateral ptosis, and in two cases there were evidences of rapidity of the heart beat and shortness of respiration, indicating an involvement of the pneumogastric nerve. Pain in the limbs was present, but not intense. The sphincters were frequently affected. In two cases in which there was no history of alcoholism delirium made its appearance; one of them ended fatally, and in the other convulsions developed. In three cases there were evidences of mild dementia. The paralytic phenomena and trophic disturbances, in these cases, run a progressive course. While amelioration is possible, in the majority of cases the condition promptly reaches a serious phase because of the extension of the pathological process to the nerves of vegetative life. The gravity of polyneuritis which develops on a soil with hepatic insufficiency is in direct relationship with the intensity of the latter. It seems that in the early stages the nerve disorder is largely due to the suppression or to a considerable decrease in the antitoxic function of the liver. In advanced stages of hepatic disturbances, when there is added an element of low general nutrition due to a cachectic state, the symptoms of neuritis are more discrete. Six cases of diabetic polyneuritis were kept under observation during a period of several years. All the patients were diabetic, with the typical characteristics of glycosuria. The neuritic symptoms, speaking generally, were those ordinarily encountered in polyneuritis of other origin. The special features, however, were as follows: Spontaneous sharp lancinating pain, cramps in the muscles of great severity and extreme tenderness of the musculature involved; cutaneous anesthesia or hyperesthesia of the distal portions of the affected limbs. In cases in which the seventh nerve was involved, pain was absent in the face, but present in the paralyzed limbs. There were also vasomotor and trophic disturbances, viz., erythemata, pruritus, falling of the nails. During the period of full development the symptomatology of diabetic polyneuritis does not differ from other forms of polyneuritis; one finds there muscular atrophy with reactions of degeneration. Another interesting feature is the great diversity of the paralysis, its incompleteness and the mode of its development.

In none of the six cases observed was the paralysis complete. Some function of the affected muscles remained intact even in the phase of full development. The course of the diabetic polyneuritis was in close relation to the fluctuation of the sugar content of the urine. When under the influence of intensive treatment for diabetic manifestations, glucose would be greatly diminished, and considerable amelioration would be observed in the neuritic phenomena. Eventually the neuritic disorder greatly improved in all cases; in two cases complete recovery was obtained, with no recurrence after a lapse of two years. The pathogenesis of diabetic polyneuritis finds its explanation, according to Gordon, in the existence of toxic products in the economy. They act on the peripheral nerves in the same manner as do toxins in infectious diseases.

1. Hematogenous Infections of the Kidney.—William J. Mayo says that Bright's disease involves both kidneys and occurs in two forms which are often confused: Type one, so-called acute parenchymatous nephritis, and Type two, the chronic interstitial nephritis. Type one is a true nephritis involving the kidney filter chiefly and is caused by specific toxins, the result of infections usually derived from lesions of the skin and mucous membranes, for example, scarlet fever and diphtheria. The kidneys are large, white and soft. In the acute phase edema from chloride retention is frequent. The urine is loaded with albumin, casts and blood corpuscles. Sometimes the disease begins subacutely and pursues a chronic course with irregular deposits of connective tissue in the kidney, and sometimes Type one nephritis is grafted on the chronic contracted organ (Type two), causing confusion of type. The chronic form (Type two) which involves the connective tissue and bloodvessels chiefly is not a true nephritis. Its cause, so far as is known, is not connected with infections, and the disease is incurable. The kidneys are contracted, hard and granular from deposits of connective tissue. The vascular system is always involved to a greater or less extent, and the heart is so often affected as to make the appellaton of cardiorenal disease appropriate in some cases. The urine is usually clear and abundant, especially at night; it is of low specific gravity and sometimes contains albumin and casts. The clinical course of the chronic form is marked by hypertension and uremia from retention of urea and other compounds. The disease may exist in the latent form for many years. Hematogenous infection of the kidney causes a third type of nephritis which, in its chronic form, has in the past been confused with Bright's disease, and in the acute form with inflammatory conditions in the abdomen. Hematogenous nephritis is an infection with living microorganisms. The disease may involve the kidneys unequally, or it may be unilateral. Congenital or acquired defects in a kidney render it more vulnerable to the infecting agents which vary greatly in virulence. In the fulminating forms, if both kidneys are involved, as with streptococcus, death results; if the involvement is unilateral, early nephrectomy may save life. In the subacute forms septic infarcts and cortical abscesses may necessitate nephrectomy, or the spontaneous evacuation of a cortical abscess in the fatty tissues may lead to a perinephritic abscess, or the whole kidney may be destroyed, causing a pyonephrosis. Since the cause of hematogenous nephritis is a pus-producing coccus of relatively short life, no living organisms may be found in the later stages and the varying results of the infection—scar tissue and other evidences introduced in the process of repair of the damage—may produce confusing pictures to the pathologist, especially if the infection is implanted on a kidney already the subject of Bright's disease. In many instances the kidney may recover its function and after this process, if painful scars remain, the pain may be relieved by capsulotomy. At times carbonate of calcium is deposited in the infected area in the process of cure; this produces *x*-ray shadows which may be mistaken for the ordinary kidney stone. The surgeon to-day is as much interested in the pathology of the kidney as is the internist, and the surgeon's work tends to bring forward the pathology of the kidney in the living for comparison with the clinical findings. Heretofore attempts have been made to correlate the clinical with the postmortem findings, which often do not show the true condition during life, but rather the terminal condition which caused death.

3. Tranquil Tracheotomy, by Injecting Cocaine Within the Windpipe.—Sir St. Clair Thomson, in order to avoid the disturbance that accompanies the opening of the trachea, employs the following method: An ordinary hypodermic syringe is charged with about 20 drops of 2.5 per cent. solution of cocaine. As soon as the tracheal rings are laid bare the syringe is grasped with the forefinger about one inch from the extremity of the needle, and the windpipe sharply stabbed between two rings. The cocaine solution is injected into the cavity of the windpipe and the needle sharply withdrawn. Ten minutes should be allowed to lapse and then incision can be made into the trachea and the cannula introduced without pain. The procedure can be employed with either general or local anesthesia. The writer has records of 25 cases of laryngo fissure in which this method has been used in performing the preliminary tracheotomy. He and his assistants have used it in dozens of cases of tracheotomy during a period of five years with uniformly good results.

2. Observations on Aortic Disease in Soldiers.—Thomas F. Cotton gives the results of the analysis of the case histories of 50 soldiers with signs of aortic insufficiency admitted to the Sobraon Military Hospital at Colchester. All of them were submitted to a complete physical examination and the exercise tolerance was determined. He states that the symptoms of D. A. H. (disordered action of the heart) so-called and in aortic cases are identical, indistinguishable the one from the other. The symptoms of early aortic disease in soldiers are not produced by the extra work put upon the heart by the valvular defect, but are due to the same causes as are the symptoms in D. A. H. In other words, disease of the aortic valve in itself gives rise to no symptoms. In aortic disease where there is venous engorgement or angina pectoris, the symptoms are not

those of aortic regurgitation, but those of heart failure. The writer's observations on exercise tolerance show clearly that aortic disease is compatible with good exercise tolerance. When there is an equal degree of distress after effort the increase in pulse rate is the same in patients with slight aortic incompetence, in aortic disease with free regurgitation where there is no venous congestion, and in D. A. H. cases in whom there are no signs of structural disease. By the symptoms alone aortic disease may be divided into three types: (1) aortic disease without symptoms; (2) aortic disease with a group of symptoms which we term the "effort syndrome" and (3) aortic disease with venous engorgement or angina pectoris. In the latter the symptoms are not those of aortic regurgitation, but those of heart failure. The characteristic picture of angina pectoris in advanced aortic disease is rarely seen in the presence of venous engorgement; with enlargement of the liver and with the onset of dropsy the pain disappears. By physical signs alone incompetence of the aortic valve may be diagnosed. The most constant sign by which one can recognize early aortic disease is a diastolic murmur, best heard at the left border of the sternum at the level of the third rib. With the development of free regurgitation, chief reliance should be placed on the character of the pulse, the collapsible, water-hammer, or Corrigan pulse. As the disease advances dilatation and hypertrophy, mainly of the left ventricle, is produced. The writer's observations do not support the hypothesis that hypertrophy in aortic disease is produced solely by regurgitation of blood through the defective valve, but favor the view that myocardial disease is the chief factor in the production of cardiac hypertrophy, and in the causation of symptoms of heart failure. Prognosis is difficult in the early stages of aortic disease. Pain, however, is an important guide in estimating the number of years remaining before the final stage of total disability has been reached. Dyspnea at rest with cyanosis and pulmonary congestion, and pain that is anginal in character and distribution and felt after slight effort, are symptoms recognized by all as indicating grave heart affection. By the size of the heart one may be helped in estimating the amount of damage which the myocardium has suffered. With the heart not much enlarged the prognosis is less favorable when the pulse is collapsing. The immediate prognosis is easily determined by submitting the patient to a simple exercise test.

3. **The Increase of the Alkalinity of the Blood in Shock.**—Benjamin Moore draws attention to recent physiological work which demonstrates that there is no enhanced acidity of the blood in shock such as would warrant the use of the term "acidosis," but rather a greatly increased alkalinity which by damage to heart and nerve centers leads to that secondary shock which produces the fatal event. Attention is called to the erroneous conclusions of a number of observers. According to the writer's interpretation, when primary shock occurs from sudden heart failure, from emotional causes, hemorrhage, pain, or some such stimulus, there is cerebral anemia and unconsciousness. There may be a recovery from this in a few minutes, but if the condition continues for a longer time, such as twenty to thirty minutes, there is a general cessation of metabolic activity at first and a shutting down later to about one-third of the normal rate. If there is a closure down in the tissues to one-third, and the lungs go on working at their normal rate or even at one-half their normal rate, an excess of carbon dioxide over that produced must be removed in the lungs and the blood go alkaline, and this is what occurs in secondary shock. As the blood becomes more alkaline it carries shock to the nerve centers and the heart. In the main surgical shock depends upon the relative rates of respiration and circulation, although other conditions, such as toxic products from wounds and muscle injury and fatigue of nerve centers, undoubtedly play a part. Hence it is an entirely wrong treatment to administer alkalies. What the organism requires is oxygen, carbon dioxide, and warmth, until oxidation in the tissues begins to approach its normal level. The writer forecasts that it will be one of the most remarkable records in medical science that for a generation scores of workers in Britain, the continent of Europe, and America went on calmly working on the assumption that by pumping off carbonic acid they succeeded in making the blood more acid.

1. **On the Nature of Rabies and Antirabic Treatment.**—Sir David Semple takes occasion to review this subject from the practical standpoint because of the present outbreak of rabies in England. He points out that whether we speak of the disease as rabies in animals or hydrophobia in man, the cause is the same in both cases and it would perhaps be better to use the terms "rabies" and "rabid" for the condition in both man and animals. Rabies is a specific infectious disease, to which all warm-blooded animals are susceptible. The cause has not yet been discovered. The saliva of man and animals suffering from the disease contains the infective agent. In addition, infection is always present in the brain-medulla, spinal cord, cerebrospinal fluid, and large nerves of man and animals suffering from rabies. The saliva of a dog may be infective for as long as five days, and in a few cases six to seven days, before any outward symptoms of the disease develop. Negri bodies are found in the brain and medulla in about 95 per cent. of rabid dogs, and while they are not truly specific of rabies their presence forms a valuable, if not absolutely certain, test for rabies. Rabies in dogs may manifest itself as either "furious" or delirious rabies, and "dumb" or paralytic rabies. While the former type is most frequent in man, the latter type is also seen. The period taken by the virus in reaching the nerve centers is variable, and depends on many factors. When bites are on the head, face, or neck, the virus has only a short distance to grow along the nerves before reaching the brain, hence it is especially important that bites in these localities receive early treatment. The incubation period of the virus of a rabid dog is fourteen days or thereabouts when inoculated on the surface of a dog's or rabbit's brain. When rabies is inoculated on the surface of an animal's brain, no subsequent antirabic treatment will prevent the onset of the disease, and presumably this fact would apply in the case of man. When a person is bitten by a rabid animal the seat of infection should receive early attention, with the object of getting rid of as much of the virus as possible. Cauterization at the earliest possible moment with undiluted carbolic acid is the most efficient and least painful application, though crude phenol, izal, lysol, or iodine, may be used. Nitric acid and the red hot iron are barbarous methods and should never be used. Cauterization certainly does no good after twenty-four hours. In any rabies infected area or country bites from apparently healthy dogs should receive the same local treatment as laid down for the bites of rabid dogs. Dogs, even though apparently healthy, should not be destroyed after having bitten persons, but should be kept under observation for a period of ten days. The chances of infection when bitten by rabid animals has been given as all the way from 16 to 60 per cent. The first symptoms of rabies which are practically always present are temperature, a feeling of unrest, and an appearance of excitement about the eyes, and, most diagnostic of all, inability to swallow fluids. It has not been established that recovery from rabies ever takes place either in man or animals. Antirabic treatment should follow local treatment as soon as possible, and this extends over a period of from fourteen to twenty-one days, according as to whether light, medium, or intensive treatment is carried out. When this treatment has been accomplished the failures rarely exceed 0.5 to 0.8 per cent., and they may be even less than 0.5 per cent. The writer urges that attendants on patients suffering from rabies be warned of the infectivity of the disease.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Twentieth Annual Meeting, Held at Atlantic City, June 6 and 7, 1919.

DR. DOUGLAS VANDERHOOF OF RICHMOND, VA., PRESIDENT, IN THE CHAIR

(*Continued from page 609.*)

Saturday, June 7—Second Day.

Questions in Relation to the Treatment of Peripheral Nerve Injuries.—Lt. Col. W. WAYNE BABCOCK, M.C., U. S. A., of General Hospital No. 6, Fort McPherson, Ga., presented this paper (see page 664).

Dr. DOUGLAS VANDERHOOF of Richmond, Va., said that war had taught much about the intelligent handling of peripheral nerve injuries. After the operative work was finished, reeducation stepped in with the use of methods which a great many of the profession had hitherto looked upon with scorn, such as electricity baths, massage, and exercise. Thus a young man with hemiplegia had regained function by playing football and basket ball; in the excitement of the game certain groups of muscles had been brought into play which would not ordinarily have been used.

Dr. H. C. GORDINIER of Troy, N. Y., said he would like to ask if there was any hope from operation after long-continued paralysis from neglected nerve operation; for instance, after a knife wound of long standing.

Dr. THOMAS F. REILLY of New York said that sweating, coldness, paresthesias, and tingling were noted after the nerve had been operated on.

Dr. W. W. BABCOCK, in closing, said that the involuntary reeducation of muscles had been worked out as a policy. The boys were sent to the physiotherapeutic department, which was furnished with the diagnosis. If there was complete paralysis of the muscles, galvanism was used. The aides were specialists in the functions of certain nerves. Thus, one had a musculospiral specialist and a sciatic specialist. These aides were usually college graduates, of higher preliminary education than the ordinary trained nurse. The making of articles of furniture, with sawing, joining, and weaving, provided all types of muscular action. The boys were encouraged in their daily progress and gradually became enthusiastic. The question of long-standing nerve injuries was very difficult to answer, but it would seem wise to give the patient the chance of nerve suture. In cases of brachial palsy from birth injuries, children had been operated on after considerable time. The cases of vasomotor disturbances, such as sweating, coldness, were very interesting. The first relief often was in the trophic disturbances. It was strange that the patient often said he felt better after the operation, long before any improvement was noted.

The Present Day Teaching of Therapeutics.—Dr. SPENCER L. DAWES of New York, presented this paper. (See page 667.)

Dr. DOUGLAS VANDERHOOF of Richmond, Va., said he remembered an interne at Johns Hopkins who was a very brilliant man, but was entirely unable to handle his patients in the medical wards. He succeeded well in laboratory investigation and was now at a research institute. Many men unfitted to handle and cure patients could find outlet for their ability in other lines.

Dr. JACOB DINER of New York said that what Dr. Dawes had said should go down to history as a war cry of physicians. The late Dr. Horatio Wood had stated that it was the duty of the physician to cure disease and alleviate pain. Another professor of medicine used to say to his students: "If you have the diagnosis, to hell with the treatment!" No doubt the diagnosis was important, but what the patient came for was treatment. Materia medica and therapeutics were neglected, pharmacodynamics was overemphasized. Class A schools gave 75 per cent. of the time to research work, but in some schools exceptions were made to this. Dr. Diner said he taught his students about the action of drugs; they had to prepare pills, powders, and mixtures. Some experimental work was done by demonstrating the effect of the drug on the student. An endeavor was made to teach them to write a prescription without committing the errors of a shotgun prescription. This type of teaching, instead of turning out investigators and technicians, turned out physicians with safe and sane medical training.

Dr. OLIVER OSBORNE of New Haven, Conn., said that most of Dr. Dawes' paper was true. At Yale they gave a pharmacology class, so that students would know about the weight, appearance, solubility, and color of drugs they were going to use. Material medica had been crowded out for the new ideas on laboratory pharmacodynamics with toxins and alkalies that would never be used in medicine. The use of medical drugs could never be learned in the laboratory. At the end of three years the men had not got the smallest knowledge of applied therapy. What could they learn of the action of such drugs as mercury, digitalis, atropine, by demonstration on animals? The speaker said he had had to fight for the proper teaching of active properties of drugs and their solubility and compatibility. The profession should treat the patient who had the disease, not the disease that had the patient. Very little time was given to the students to learn these things. Some surgeons combined medical knowledge of drugs with their work, but most had no interest in the patient after the operation, and patients were often made very uncomfortable by ill-advised giving of hypnotics.

Dr. C. E. DE M. SAJOUS of Philadelphia said that some years ago he visited Harvard University and saw the department of pharmacology, which cost $350,000 to construct. The course was optional and he asked the director how many men patronized the course, and was told that ten men out of 450 students had taken the course. At the University of Pennsylvania pharmacology was admirably taught. The American Medical Association was not doing the right thing by the public in this respect. At the present time the scientific teaching was beyond the needs of the public. The profession had the public to take care of.

Dr. F. M. POTTENGER of Monrovia, Cal., said that the function of the physician was fourfold: Prevention of disease, cure of the illness, relief of pain, relief of inefficiency. Modern medicine was looking most toward the prevention of disease, but at the same time, as long as the human race would last, there would be disease and pain to be relieved. Thus there would always be many buyers for what the profession had to sell. It was calculated that every person lost at least ten days of life through illness each year; thus the amount of time lost in a population of 100,000,000 was immense. There were defective cases and hopeless cases to treat. These were not really hopeless and therapeutic measures could be applied. One of the great mistakes of the profession was in being too narrow. This restriction had made Christian Science necessary and osteopathy necessary. The medical man had seen nothing on one side or another, and therefore had lost his patients. People wanted relief; they did not care whether the diagnosis was correct or not. The profession wanted an accurate diagnosis because then therapeutics could be accurate. Men became so skillful in diagnosis and pathology that they forgot the needs of the patient. All sorts of specimens were examined and nothing done for the patient, who naturally went away. The profession had the basis for all the cults, if men could use it. It was an outrage to be called "drug doctors", but it was because the profession had neglected the use of other measures—dietetics, rest exercise, very little use was made of these. The old teacher thought of drugs only. The modern teacher did not think of drugs, he thought of nothing. The profession had to take in anything that would be of benefit to the human race, because they were big enough to do it, because they had the right guidance to apply it.

Dr. HORATIO WOOD of Philadelphia said that Dr. Dawes was a very good diagnostician, he had told them what was the matter with the body medical, but he had not suggested any remedy. Many of them had seen this disease progressing for a long time, yet one had felt the hopelessness of its treatment. Something might be done, however. In New York City museums the armorers who repaired armor of the middle ages had become very important adjuncts of modern means of defense. One would not suppose that helmets, breastplates, and tincan accouterments of ancient knights would have been applied to modern necessities, but it might be that

the time would come again when doctors would recognize that medicine had its place in the world.

Dr. THOMAS F. REILLY of New York said that Dr. Sajous had hinted at the remedy, or rather at the cause of the disease, which originated in Chicago. That was where pressure was being made to eliminate teaching of medicine. Too much was attempted. One could not turn out a physician to make a diagnosis of all the "pathies" in four years. One must first teach principles, and it was hard enough to do that, but it was necessary before allowing a man to practise on his fellow beings. One great reason why therapeutics was pushed aside was that it was pure memory work for the student. The tendency in America today was to do as little mental work as possible. The physician, however, who could not cure his patient could not succeed.

Dr. DAWES, in closing, said that he was gratified by the commentary on such an unscientific paper as he had presented. As to the cause, while he agreed to a certain extent with Dr. Reilly as to the pressure from Chicago, he felt the cause really lay with themselves; by themselves he did not mean himself, nor Dr. Osborne, nor Dr. Diner, because they had tried to teach these subjects for many years. The other men supposed that books on materia medica were recommended by some publishing house, and when they found the specialists prescribed proprietory remedies they threw away their books on therapeutics. Which of the men present had the latest edition of the U. S. Pharmacopeia, and if he had it did he use it? Which man went to pharmaceutical conventions, or who supervised such meetings? At the last pharmaceutical convention a noted man was questioned as to eliminating many useless drugs from the pharmacopeia; he said "not at all, let's enlarge it." I would put in brick-dust if anyone would take it." That man was a teacher of therapeutics. As to Dr. Wood's remark regarding the remedy for this condition—far be it from him to prescribe in a company of clinicians and therapeutists.

The Proportionate Dose of Quinine Required to Produce the Same Results in Treating Malaria in Children of Different Ages, as in Adults.—Dr. C. C. BASS of New Orleans presented this paper. No two text-books on malaria gave the same treatment, unless one copied from another. The dose for adults was stated as from 10 to 40 grains, but that for children was very indefinite. There were two ways to control malaria: one by destroying mosquitos; the other by controlling the parasite in man. Malaria could be eliminated from a locality by whichever means was most practical. In large areas the disinfection of persons was more practical than ditching and draining. In an area of the Mississippi Valley, with a population of 31,459 persons, the highest percentage of infection was in the 5 to 10-year group, and most malaria was in persons under 20 years of age. By ordinary means of treatment few persons were thoroughly disinfected, and would subsequently relapse. Relief of clinical symptoms did not mean disinfection. Experiments as to dosage in different proportions and by different methods were carried out by the International Health Board, and later reexamination was done to see the effects of the experiments. A dose of 1/20 of the adult dose was tried for children, but it was found that more adults than children were cured, therefore, the children's dose was too small. A table of dosage was then worked out by ages: 1 year, ½ grain; 1½ years, 1 grain; 2 years, 2 grains; 3 to 4 years, 3 grains; 5 to 7 years, 4 grains; 8 to 10 years, 6 grains; 11 to 14 years, 8 grains; 15 (adult dose), 10 grains. Ten grains of quinine every night for eight weeks disinfected 90 per cent. of all infected persons. The remaining 10 per cent. had to have three 10-grain doses a day for three or four days, and later 10 grains a day for eight weeks. The amount of quinine taken was the only criterion as to disinfection of the infected individual.

Dr. DOUGLAS VANDERHOOF of Richmond said that there was not an excessive amount of malaria in Virginia. Although there were excellent physicians throughout Virginia he believed they had yet to see a case of malaria treated to the point of disinfecting the patient. The doctor generally thought he had done his duty when he had relieved symptoms. For the sake of the community the patient had to be disinfected. Personally he gave routine directions to malaria patients, covering three weeks and then nine weeks. A good deal of harm was done by giving proprietary medicines containing small doses of quinine, by which means the malarial parasite became to a certain degree resistant.

Dr. JACOB DINER of New York said that there was little difference between quinine sulphate and muriate, except as to palatability for the patient. In giving quinine to children, one should not use condensed milk, as that tended to create a distaste for milk and deprived the child of a staff of nourishment. The stimulation of taste-buds was caused by solution. Therefore, if given in an insoluble form, such as alkaloid, salicylate, or tannate, it would accomplish the purpose just as well as the syrup of licorice or chocolate syrup; the latter as sold in drug stores often contained only one grain per dose.

Dr. HORATIO WOOD of Philadelphia said that Dr. Bass's paper was very instructive. In the North not much malaria was seen. The question of dosage for children opened an interesting problem. Dr. Bass based the dosage on the age of the child. Cowling and Young approximated the weight of the child. A doctor should be able to guess the weight of the child, and this was the proper way. Where therapeusis was carried out in such a wholesale manner this might be difficult. It was interesting that insoluble salts were absorbed as readily as soluble salts. In regard to disguising taste, the taste glands, if stimulated by one impulse, perceived another impulse less. Sweet disguised bitter. The taste of quinine could be disguised by putting it in a suspension of gum acacia. The speaker said he had treated malaria patients for two or three days with quinine and then given methylthianin which had a decided antiperiodic effect, especially against the gametes. It might be found that the parasites became quinine fast by developing a resistance.

Dr. H. C. GORDINIER of Troy, N. Y., asked how one should handle infections of the brain, with coma.

Dr. J. B. WHITE of New York said that two things were important, the treatment of the paroxysym and the prevention of recurrence. Small amounts of quinine could be given before the paroxysm, to allow of assimilation, and 30 to 40 grains during the paroxysm. With a mixed paroxysm, such as double quotidian or double tertian, this was difficult; 20 grains three times a day was better then. Perhaps the preponderance of cases noted in early years might be because older persons had received previous treatments which lessened the occurrence in later years.

Dr. DOUGLAS VANDERHOOF of Richmond said that in regard to the solubility of quinine, he could remember, as a fourth-year student, a very shocking incident. A patient came in moribund. The physician had given enormous doses of quinine without controlling the disease. The blood showed an unusual picture. Every other red-blood cell contained one or more parasites. The patient died in twelve hours and came to autopsy. A large ischiorectal fistula was discovered and this contained more than sixty quinine pills, practically unchanged. The speaker therefore concluded that quinine should be given in solution, and he had prescribed quinine sulphate in dilute hydrochloric acid. If the matter was explained to the patients they generally took it without complaining.

Dr. C. C. BASS, in closing, said that after giving small doses of quinine one could find the gametes, or resistant forms, present in the blood. Some workers believed that these could reproduce. They could infect mosquitos and these transmitted the disease. When gametes were wanted in the laboratory they gave doses of "chill tonic", containing the asexual form of the parasites, and that brought out the gametes in seven days. Giving a patient insufficient quinine increased the probability of transmission of the disease. The minimum dose was 10 grains for disinfection. As to salts, experiments had proved that no salt was superior to the ordinary sulphate. Solubility or insolubility seemed to be immaterial, whether given in solution or out of solution. It would be impossible to persuade people to take quinine in acid solution over a long period of time. Doctors who recommended this should try the dose themselves first. People were familiar with the sulphate of quinine and a new type of dose would make them sus-

picious. Capsules or tablets were the best form. Experiments with gastric juice showed that tablets dissolved quicker than the capsules. Children did not swallow tablets well, and for them solution in aromatic syrup was best. In regard to age versus weight, age was chosen as a standard because this was the thing people knew most about. They always remembered their birthdays. A slight error would not be very material. As to methylene blue, all cases, except moribund cases, could be treated by quinine sulphate better than any other means; therefore, except in exceedingly rare cases, there was no reason for complicating the treatment. In regard to quinine-fast parasites the existence of such had not been proven, but it might be true with increased production of gametes. In checking up results twice, the same proportion of disinfected persons was found the second time as the first. The evidence of disinfection was by blood examination and by history of attacks. The absence of symptoms and of parasites was put down as a positive result. Coma was due to a large number of parasites lodging in the capillaries of the brain and shutting off the circulation. Quinine put into the circulation would not get there, regardless of any treatment employed. Quinine should be put in intravenously, but that might not save all cases. In regard to the paroxysm, it was not necessary to wait till the patient was going to have a chill to start the treatment. The moment the diagnosis was made was the time to put in quinine, and it should be kept up from that minute on. One reason why quinine did not immediately stop the chill was that the parasites lodged most of the time in the capillaries; as they reproduced they came out again, so that it was necessary to keep on with quinine for eight weeks. As to immunity, the figures showed that at least 50 per cent. of the population in the locality studied had had malaria, and lasting immunity was not produced there, nor, the speaker believer, did it occur anywhere else.

(To be continued.)

Miscellany.

Death of Hallopeau.—This distinguished French dermatologist, recently deceased, was born in 1842, and was educated at the Condorcet Lyceum, where he had as schoolmates numerous boys who later distinguished themselves in medicine. A student at the University of Paris he had as masters men like Vulpian, Charcot, and Jaccoud, and his earliest efforts were in the direction of neurology. He produced works on spinal convulsions, myelitis, and bulbar paralysis. His thesis for an aggregate professorship in 1878 had for its subject the therapeutic action of mercury and he wrote other important papers on drug action. In 1884 he published his treatise on general pathology and pathological physiology, which has gone through six editions. In the same year, for the first time, he took up dermatology, although he had long been an assistant to Hardy, known equally as internist and dermatologist; and from that time on he specialized entirely in diseases of the skin. With Leredde he issued in 1900 a classical work on this subject. He especially favored certain diseases which he studied faithfully throughout his entire sphere of activity. One of these was mycosis fungoides with special bearing on its early, obscure stages. Other diseases which he studied were mostly rare and obscure and devoid of great practical significance. Aside from these activities he made valuable contributions to our knowledge of farcy in man, of leprosy, and of tuberculosis of the skin. Such a man was certain to distinguish himself as a syphilographer and he anticipated Ehrlich in the notion of aborting syphilis by intensive early treatment (with atoxyl and hectin). Nothing is said of his opinion of salvarsan. In fact little is said of his last years and it is probable that he retired from an active life some years ago as a result of his age. His career is a fine example of an eminent specialist who devoted nearly twenty years to clinical medicine and neurology before settling down to his single field of dermatology.

Toxicological Laboratories.—Peset of Valencia writes on this subject with special reference to local conditions. The term commonly suggests detection of criminal poisoning but of late years has taken on a new aspect because death from food poisoning may imply contributory neglect on the part of the State. Of subjects which belong here the first mentioned is poisoning from certain spoiled foods—milk, shell-fish, etc. Of great importance is the prevention of death from poisonous mushrooms. The intimate nature of food poisoning is not yet intelligible. Why can rabbits and snails thrive on belladonna, goats and rats on poison hemlock, and domestic fowls on Spanish flies? Poisoning from spoiled meat is due to the pathogenic germs which flourish upon it and the action of the socalled ptomaines is only mentioned in passing as a special form of intoxication. The author in the same connection mentions the presence of subtle toxalbumins formed by metabolism in connection with the action of molds and the blow fly. In a word putrefaction sets free a myriad of toxic agencies which differ much among themselves and which future food laboratories must clear up.—*El Siglo Medico.*

The Influenza Pandemic in Portugal.—We have heard but little of Portugal in connection with the pandemic although the statement is common that the disease "ravaged the Iberian peninsula" as was to have been expected. In the *Office International d'Hygiène Publique* for April last, Jorge publishes an elaborate report in which he describes the two waves which swept Portugal. The first extended from the first days of June to the middle of July, and was known as Spanish influenza; was fugacious, benign and uncomplicated. The second wave was active from the middle of August to the end of November and was termed influenzal pneumonia. Before the first wave could have arrived at the Portuguese frontier the disease had already been carried to Lisbon and Oporto by returning travelers from Madrid. From these centers it was rapidly diffused over the country by travel routes. The second outbreak in mid-August began in Oporto as a series of cases of pneumonia, which suggested the lung pest. To the author it vividly recalled an episode of 1896 when in Oporto the ordinary grippe took on a malignant pneumonic form. This episode occurred in the spring and summer and hence differed by that much more from winter grippe. The entire report goes extensively into the history and nature of influenza and many features are brought out. The term "Spanish grippe" is very old and has been used in previous pandemics. In this connection it may be recalled that Herbert Spencer once prophesied that if the great plagues were stamped out influenza would replace them as a scourge of mankind.

THE PRESENT STATUS OF VACCINATION AGAINST INFLUENZA.*

BY F. E. STEWART, M.D., PHAR.D.

PHILADELPHIA, PA.

Is vaccination of any value in preventing influenza? This question cannot be properly answered until, during an epidemic of the disease, two bodies of people, equal and sufficient in number, one composed of vaccinated individuals, the other of unvaccinated individuals, are exposed to contagion under the same conditions of environment. Opinions regarding the present status of vaccination as a preventive of influenza will be influenced by other factors both theoretical and practical until such tests are made. These factors pertain to the symptomatology of the disease, and especially as to its cause, and also to the history of bacterial vaccines in the prevention and treatment of sporadic influenza, pneumonia, and other affections of the respiratory organs previous to the great influenza pandemic of 1918-19.

Those who believe in the microbial etiology of epidemic influenza—and the majority of physicians do so believe—are divided into three different camps, namely: Pfeifferites, non-Pfeifferites, and those who believe that influenza is due to a mixed infection, caused by the group of bacteria commonly known as the mouth bacteria, which microbes, owing to unknown conditions relating to the organisms themselves or to their hosts or to both, become pathogenic and readily transmissible with increasing virulence, causing the great pandemics of influenza, which from time to time have extended over the world.

There are also several opinions regarding the value of bacterial vaccines as agents for the prevention and treatment of affections of the respiratory organs as a general proposition. The skeptics base their opinions largely upon the assertion that no immunity to subsequent attacks is conferred by a "cold," an attack of grippe, or of pneumonia, but, on the contrary, greater susceptibility results; therefore, the claim is absurd that vaccination can be effective against these infections by injecting the modified bacteria found in these diseases.

If this opinion had been the unanimous verdict of the medical profession, the story would have ended right here. But it is not. On the contrary the good record made for vaccines and serums in the prevention and treatment of respiratory affections, including pneumonia, convinced many physicians of eminence of their value. Yet many other physicians of like eminence remained unconvinced; consequently, when the late epidemic reached our shores from Europe, where it had been raging severely for some time, the opinions of physicians on this side of the water were unsettled as to the value of such vaccination.

The skeptics were strengthened in their position by the uncertainty regarding the identity of the initial invader, and their opposition was further encouraged by the nonsuccess of Park's vaccine in New York City. He prepared a vaccine from the *Bacillus influenzæ* which was distributed gratuitously and quite extensively to the physicians in New York City by the Board of Health. The results seem to have convinced the profession that vaccination against epidemic influenza by using the modified influenza bacillus cultures as antigen, is practically of little value.

The belief has been expressed by some writers that the epidemic was possibly a form of the bubonic plague. However, it has been pointed out that, except for its high virulency and mortality, the disease closely resembled that of the 1889-1890 epidemic of influenza.

Let us now briefly consider the history of the introduction of bacterial vaccines as prophylactic and therapeutic agents in the treatment of respiratory affections, prior to the arrival of the influenza epidemic to the shores of the United States.

Dr. A. Parker Hitchens, a member of this society, and during the war engaged in the U. S. Army Medical School in Washington, conducted an exhaustive research to determine the character of the infections causing the various diseases of the respiratory organs. This research work was conducted in cooperation with several of the clinicians connected with the hospitals in Philadelphia, who supplied the material for cultures, taken from the sputa, throat, and nasal passages of patients under their care, These investigations were reported in a paper read by Dr. Hitchens before the Medical Society of the State of Pennsylvania, Scranton session, Sept. 25, 1912, entitled, "The Bacteriology of Catarrh and Common Colds." Hitchens stated that the species of bacteria found by him and others in the specimens from the nose and throat of persons suffering with acute catarrh are the influenza bacillus, pneumococci, staphylococci, streptococci, diphtheroid bacilli, and Gram-negative cocci classed as *Micrococcus catarrhalis*. Other forms occur in rare instances, but apparently have no special significance. The *Micrococcus catarrhalis* and those resembling morphologically the diphtheria bacillus were almost invariably present.

*Read at the twentieth annual meeting of the American Therapeutic Society, held at Atlantic City, N. J., June 6 and 7, 1919.

Dr. Hitchens accordingly suggested the following formula for the treatment of influenza and common colds: Each mil (c.c.) contains: *B. influenzæ*, 100 million; *Staphylococcus aureus*, 400 million; *Staphylococcus albus*, 400 million; *Streptococcus hemolyticus, viridans*, and other types, 100 million; pneumococcus (types I, II, III, and IV), 100 million; *M. catarrhalis*, 100 million.

I do not mean to say that Dr. Hitchens was the first to suggest such a formula. R. W. Allen, M.D., B.S., in his "Vaccine Therapy: Theory and Practice," the first edition of which appeared in 1907, ascribed the diseases of the respiratory organs, including influenza, to mixed infections by a similar group of bacteria and said that the "etiological cause of the entire list of these affections comprises a group of microorganisms, more or less varied in character, to be sure, but practically the same in membership." Dr. Allen recommended and claimed to have used successfully mixed antigens of this character in the treatment of diseases of the respiratory organs.

As a result of the investigations made by these observers, mixed antigens of similar formulas were placed on the market by the great manufacturing houses supplying biological products in this country and abroad. Millions of doses were administered prior to the influenza epidemic of 1918, and the results following their use in the prevention and treatment of common colds, bronchitis, and sporadic influenza were sufficiently favorable to convince many of the leaders of the profession of their value, so that in the beginning of the recent influenza epidemic there were competent medical authorities on both sides of the water who advocated vaccination to combat it.

However, the medical profession has always been noted for its ultraconservative attitude in regard to everything new. Therefore, it is not surprising that many equally competent observers were unconvinced of the value of these mixed antigens as prophylactic and therapeutic agents.

Some of the skeptics objected that immunity against respiratory diseases, including pneumonia, is, as already stated, theoretically impossible to obtain by vaccination on the ground that no immunity is conferred upon the individual by an attack of these diseases. Advocates of bacterin therapy answer that immunity to furunculosis does not follow boils, but it is generally conceded that staphylococcus vaccine gives excellent results in this treatment.

As pneumonia is the disease attracting the most attention in relation to influenza, let us consider whether immunity can be secured against pneumonia by vaccination.

You, of course, are fully conversant with the researches of Sir Almroth E. Wright in the Gold and Diamond Mines in South Africa. As pointed out by the *Lancet*, April 13, 1918, the results of these investigations were valuable as the remarkable reduction in the mortality of pneumonia among the native mine workers fully demonstrated.

You are also fully conversant with the work of Mr. F. S. Lister, bacteriologist of the South Africa Institute for Medical Research, who demonstrated that three subcutaneous inoculations with the triple vaccine of the three groups prevented the occurrence of pneumonia as caused by members of these groups. Lister found that his own serum, following vaccination, contained agglutinins and opsonins against the type of organism injected eight months after the last inoculation.

You are also familiar with the work of Avery, Chickering, Cole, and Dochoz at the Rockefeller Institute for Medical Research, published in Monograph No. 7, of that institution. These investigators also proved that immunity to pneumococcus pneumonias may be obtained by using sera from animals immunized against certain types of these microorganisms, also that these bacteria confer immunity in humans when used as vaccines.

The following memorandum was issued to officers, enlisted men and employees in the War Department during the winter of 1918-19: "Vaccination against pneumonia has been given in two army camps. At Camp Upton during the ten weeks from the period of vaccination until the troops went overseas, no cases of pneumonia due to the type of pneumococcus protected against Types I, II, and III occurred among the vaccinated troops. The incidence of pneumonia from other organisms was only one-tenth as high among the vaccinated as among the unvaccinated, although previous to vaccination the incidence of pneumonia has been equal in the two groups."

The next objection urged by the skeptics was that the employment of mixed vaccines containing a number of microorganisms assumed to take part in diseases of the respiratory organs is unscientific. It is, of course, admitted that each disease has a specific cause, and that the microorganism causing a disease should be isolated and used in preparing the vaccine to combat it. However, when the specific cause of a disease characterized by a mixed infection is unknown, why not immunize against the secondary infections? This method was recommended and was very generally adopted by the advocates of vaccination during the recent influenza epidemic, as the following and many other reports from authoritative sources will show.

The *British Medical Journal* for Oct. 14, 1918, published an account of the proceedings of a conference, which was presided over by Col. Sir William Leishman of the British Army, whose wide experience in the immunization of the troops is, of course, well known. It was unanimously agreed that inoculations with a suitable vaccine might be expected to be of value, for both prevention and treatment. It was agreed that the vaccine should contain *B. influenzæ*, the pneumococcus, and the streptococcus, and that a number of different strains and types of each organism should be utilized in the preparation, also that these strains should have been recently isolated from cases occurring during the epidemic. A mixed antigen was recommended containing *B. influensæ* 90 million, pneumococcus 300 million, and streptococcus 160 million. The initial dose recommended was one-third of the entire amount, the remainder being given as the second dose at the end of ten days. As regards the conditions under which this prophylactic vaccine should be employed, the conference was unanimous in deciding that whilst it would be preferable to carry out the inoculation before exposure to infection, there do not exist any adequate

grounds for withholding it in the case of a body of men among whom influenza has already appeared.

Another report from English authority was confirmatory to the above:

Surgeon Captain P. W. Bassett-Smith, R. N., reported on a mixed bacterin containing *B. influenzæ*, streptococci, and pneumococci. This bacterin was distributed to the depots and to ships of the Grand Fleet, to be given to all on a voluntary basis. At Greenwich, 1000 boys of the Royal Hospital School received two inoculations. No case of influenza occurred among them, though the disease was prevalent in the district.

Captain F. L. Armitage* used the mixed bacterin both for prophylaxis and treatment. For prophylaxis a bacterin was employed containing various strains of the pneumococcus, streptococcus, *B. influenzæ. Staphylococcus aureus, M. catarrhalis, B. pneumoniæ and B. septus,* as recommended by Lowe and Eyre. Of the 247 persons inoculated, including physicians, orderlies, nurses, etc., in charge of the large number of patients admitted to the hospital with influenza, no cases of pneumonia developed, and but few cases of influenza or cold.

Captain W. E. Carnegie Dickson, at a meeting of the fellows of the Royal Society of Medicine, Nov. 23, 1918, stated that he used the mixed bacterin prophylactically in about 159 cases, and so far as he had ascertained, only two had developed anything resembling influenza, and these were light cases. In the cases without pneumonia complications, the disease appeared to be shortened.

Dr. E. C. Rosenow, of the Mayo Foundation at Rochester, Minn., read a paper at the meeting of the American Public Health Association on "Prophylactic Inoculation Against Pneumonia and Influenza." As is well known, Rosenow employed mixed bacterins in the treatment of respiratory affections prior to the influenza epidemic. In referring to his bacteriological findings during the epidemic, he called attention to the mixed character of the infection. He found the several types of pneumococcus, the hemolytic and other types of the streptococcus, the staphylococcus, influenza bacillus, and other organisms, including the green coccus and the *Micrococcus catarrhalis.* He also reported the results he had obtained by the employment of a mixed antigen made up in the following proportions: 30 per cent. pneumococci; 30 per cent *Streptococcus viridans;* 20 per cent. green coccus; 10 per cent influenza bacillus; 10 per cent. staphylococci.

The attack rate after injections was 23 per 1000, after the first; 10 per 1000 after the second, and 9 after the third; control 220 per 1000. Pneumonia, 2 per 1000 after the first; 1 after the second, and 1 after the third; control 14 per 1000. He said that the protection afforded by the vaccine lasted at least six weeks. He was of the opinion that the initial state of the disease is due to some unknown virus.

In discussing Dr. Rosenow's paper, Dr. F. O. Tonney, of Chicago, who spoke for the Department of Health, said that they were in such straits in Chicago with increasing cases and deaths from the disease that Dr. Rosenow, of Rochester, was called upon for assistance, and upon his arrival began the preparation of the vaccine, according to the above formula. Of 44,494 not vaccinated there were 1,039 cases of influenza, with 95 pneumonias and 60 deaths. Of the 2,584 vaccinated cases, those receiving the first injection only developed 14 cases of influenza. The 1,636 receiving the second injection developed no cases. The 1,201 receiving the third injection developed no cases. There were three cases of pneumonia in this group, but no deaths.

Similar reports in regard to the efficacy of vaccination against influenza and the complicating pneumonias were presented to the Philadelphia County Medical Society during the symposiums on the subject, held Oct. 9, 23, 28, and Nov. 27, 1918.

Professor John A. Kolmer, M.D., D.P.H., of the University of Pennsylvania and the Philadelphia Polyclinic, who, in discussing the subject before the Philadelphia County Medical Society, in the symposium already referred to, said that his studies justified him in the belief that the *B. influenzæ* and streptococcus were the principal infecting organisms in the epidemic in Philadelphia.

Lt. Russell S. Bowles, of the Medical Department of the Navy, reported the results of treatment of 525 cases of influenza and pneumonia occurring at the League Island Navy Yard. In only 50 of these cases were vaccines employed. He said that striking improvement was noted, especially if the bacterin was used early. Only two of the patients developed complications, the complication being pleurisy. None of the men immunized against influenza took the disease.

Experiments were conducted at Camp Zachary Taylor, Louisville, Kentucky, by Major Herbert Fox, M. C., U. S. Army, and reported in the *Journal of the A. M. A.*, Nov. 16, 1918. The object of his experiments was to ascertain the effects of the mixed antigen upon the leucocytes. He found that there was a drop in leucocytes from six to twelve hours followed by a rise at the end of eighteen hours, sometimes to 300 per cent.

The South Department of the Boston City Hospital reported 46 vaccinations, none of which was followed by influenza. On the other hand, of the remaining 88 attendants and patients, 28 contracted the disease—about one-third.

The following abstract of a paper from Major J. Pratt Johnson, Director of the Clinical Research Laboratories, Johannesburg, South Africa, in a recent contribution entitled, "The Pneumo-Catarrhal Diathesis, Prevention and Treatment of Pneumonia and Other Respiratory Infections by Mixed Vaccines," which appeared in *American Medicine,* March, 1919, p. 149, is of special interest:

The majority of cases diagnosed as pneumonia are due from first to last to a mixed infection in which pneumococcus may or may not be included. Briefly, the evidence which is accumulating as to the value of therapeutic inoculation in cases diagnosed as pneumonia with a mixed vaccine prepared from numerous strains (150) of *M. catarrhalis,* streptococcus, pneumococcus, *B. friedlander,* and staphylococcus, indicate that whatever objections may be raised to the etiology of pneumonia, as set out above, the clinical results fully justify this statement. Prophylactic inoculation of a stronger vaccine from these organisms has similarly given most gratifying results in preventing the onset

*"Note on 'Influenza' and Pneumonia," from a field hospital, by Capt. F. L. Armitage, N. Z. M. C., bacteriologist to the New Zealand Stationary Hospital, British Expeditionary Force, France. *Brit. Med. Jour.,* Nos. 23 and 30, 1918.

of pneumonia, the mortality in inoculated cases which have contracted influenza being trifling.

The prevalence of pneumonia in South Africa during the weeks in which the influenza epidemic raged throughout the land has been very marked, the appalling mortality being almost entirely due to pneumonia. Numerous examinations of the sputum have demonstrated that the symptoms are due to a mixed infection, the virulence of the organisms being enormously raised by rapid passage so that many of the cases are septicemic in type. The employment of the above mixed vaccine in these cases has been the general practice throughout South Africa for some time and, judging from personal observation and numerous reports received, the results have been astounding. Numerous cases ill with pneumonia for weeks have, after one or two injections, shown a normal temperature and pulse, and made, in the circumstances, a rapid uninterrupted recovery. The mortality from pneumonia has also been enormously reduced by therapeutic inoculation with a mixed vaccine. One practitioner reports over a hundred cases and another two hundred cases of pneumonia treated with mixed vaccine without a single death.

The use of a comprehensive mixed vaccine for the treatment of respiratory infections, including pneumonia, largely relieves the clinician—who is often without the aid of an experienced bacteriologist—of the responsibility of deciding in his own mind the bacteriology of the case before him. No matter what respiratory diseases the patient may be suffering from, whether tonsillitis, bronchitis, bronchiolitis, bronchopneumonia, pneumonia, pleurisy, etc., such a vaccine prepared on such lines would be distinctly applicable. The very simplicity of this line of action must commend itself to the medical practitioner by whom the bacteriology of respiratory infections cannot be decided without some difficulty.

A constitutional weakness in the elaborate defensive organization against invation by the causative microorganisms of respiratory diseases indicates a pneumocatarrhal diathesis. This constant diminished resistance can be successfully reversed by specific immunization with a highly multivalent mixed vaccine prepared from numerous recently isolated virulent strains of these pathogenic bacteria commonly conveyed in the air breathed. Nonspecific treatment is of no avail.

Prophylactic inoculation with mixed vaccine prepared from the organisms enumerated will enormously reduce the incidence of pneumonia and other respiratory diseases (excluding tuberculosis) and largely abolish the mortality from these diseases. The actual composition of the vaccine and proportion of each organism represented in the mixed vaccine used should be decided from a close and extensic study of the bacteriologic flora found in respiratory diseases.

Now, in regard to the duration and degree of immunity produced by the vaccination. Dr. E. C. Rosenow, as already stated, said that protection afforded by the mixed antigen lasted six weeks. Upon what data he based his observation, I do not know.

Two important factors should be considered in this connection, namely, the variability of the secondary infection associated with the influenza, which determines the occurrence of complications and mortality of the disease, and the degree of immunity to be obtained against respiratory diseases either as a result of the disease itself or as a result of vaccination. Referring to variability of the secondary infection, as pointed out by the *Lancet* for April 5, 1919: "Not only are separate epidemics or separate waves of the same epidemic associated with different secondary infections, but the latter would appear to vary substantially during the progress of the epidemic. In the recent pandemic, for example, the *Bacillus influenzæ* was demonstrated as present in a large proportion of cases followed by severe secondary symptoms due to the pneumococcus. In other localities the various species of the streptococcus appeared to be the most important microorganisms in the secondary infection, and still in other localities the influenza bacillus was not found by competent bacteriologists."

Referring to the degree of immunity conferred by respiratory diseases, I have called attention to the researches of several well-known investigators who demonstrated that immunity to pneumonia may be produced by vaccines and serums; and it is believed by many physicians that immunity to common colds may also be thus obtained. But it is probably true that immunity to the respiratory diseases is a light one at best, lighter, for example, than the immunity obtained by vaccination against typhoid fever, which, in turn, is a lighter immunity than that obtained by vaccination against smallpox.

Is it not possible that these two factors account in part for the great divergence of opinion between physicians of eminence, concerning the value of vaccination as a preventive of influenza, or, more properly, its value as a preventive of the secondary infections? Many reported that vaccination produced fairly good results, others reported that vaccination is valueless, and still others reported that the immunity obtained, while insufficient to prevent either the influenza or the complications due to secondary infections, yet the course of the disease was "so modified that lower mortality resulted, even in severe cases."

Conclusions and Comments.—It would seem to me that the present status of vaccination against influenza may be fairly stated as follows:

1. The recent pandemic of so-called influenza was due to an undetermined "influence" that lowered the resistance of the body as a whole and of the respiratory organs in particular.

2. The Pfeiffer bacillus is regarded by some authorities as the primary infective agent, while others assign to it a secondary role as contributing to the clinical manifestations or complications.

3. Whether or not the influenza bacillus of Pfeiffer plays the role of a primary or secondary infective agent, the fact remains that the following bacteria are considered mainly responsible for the pneumonias and high death rate which accompanied the pandemic or influenza. This group consists of the *Bacillus influenzæ* of Pfeiffer, different types of the pneumococcus and different varieties of the streptococcus, the *Staphylococcus albus* and *aureus*, and the *Micrococcus catarrhalis* group. Sometimes, other kinds of bacteria take part in the infection.

4. This group of bacteria is also responsible for the various infectious respiratory diseases known under different names, depending upon the anatomical structures attacked. Thus we have the terms, coryza, cold in the head, influenza, tonsillitis, bronchitis, pneumonitis, lobar pneumonia, bronchopneumonia, etc.

5. According to the evidence above cited, vaccination against these several so-called respiratory diseases has proved of decided efficiency both for prevention and treatment. This evidence was accumulated by competent observers during the prevalence of the influenza epidemic in the army, navy, great industrial institutions, and in private practice, both in this country and abroad, during the great war.

6. Failures may result unless proper care is exercised in preparing the vaccine. A highly multivalent mixture vaccine prepared from numerous

virulent strains of the bacteria comprising the group responsible for the respiratory diseases should be employed. Early failures were largely due to the employment of a vaccine prepared from the Pfeiffer bacillus alone, later failures to the use of a combination of this bacillus with the pneumacoccus. Subsequent successes with vaccine prepared from the whole group demonstrated its greater efficiency.

THE TREATMENT OF INFLUENZA AND OF THE COMPLICATIONS INCIDENT THERETO.*

By JACOB DINER, M. D.,

NEW YORK

PROFESSOR OF PHARMACOLOGY, THERAPEUTICS, AND CLINICAL DIAGNOSIS, FORDHAM UNIVERSITY SCHOOL OF MEDICINE.

I WISH to state at the outset that I have no panacea for the treatment of the above named conditions. Nor does the paper mean to imply that we implicity followed the routine outlined here. Very often treatment was varied to suit conditions. At all times we treated the patient rather than the disease.

It is assumed that everyone is acquainted with the general symptoms associated with an influenzal infection. It is also presupposed that a blood count has been made and the presence of a leucopenia established. As soon as the patient is admitted to the ward he or she is put to bed. Right here let me voice a protest against the generally adopted method of freezing or chilling the patient. While it is true that fresh air is a very important factor it is equally true that cold air is harmful if not dangerous to our patients. Proper ventilation should and can be maintained without going to extremes. The temperature of the room should never be below 65 deg. Fahrenheit and a degree or two above that is by no means a drawback. Of the hundreds of cases observed by me during the 1918-1919 epidemic this has been impressed on me very forcibly both by the general condition of the patients and by the temperature, pulse, and respiration curves. Furthermore the patient should be well covered with woolen blankets, chosen with a view of warmth rather than weight. It is best that the patient's body should not come into direct contact with the blankets. Linen sheets should be interposed so that frequent change may thus be effected without inconvenience to the patient.

Before the patient is put to bed a warm bath is given, care being taken not to expose the patient to drafts either in the bathroom or on the journey to or from the same After the patient was properly bedded our routine treatment consisted of the following: Ten grains (0.6 Gm.) quinine sulphate and a like amount of Dover's powder are administered at one time, followed by a hot lemonade to which, according to circumstances, half an ounce (15 c.c.) of whiskey may be added. A hot water bag is applied to the feet, the patient is well covered, the room is darkened, and all but the nurse or attendant are excluded from the room. Should the patient remain awake hot drinks, either tea with milk or milk alone, are given at frequent intervals, at least every three hours. During the diaphoresis, which generally ensues, the patient should not be disturbed, not even for the purpose of taking pulse or temperature. As a rule copious sweating soon sets in, particularly if a sufficient amount of hot fluid is given. Should this fail to appear we administer five grains (0.3 Gm.) of quinine and two and half grains (0.15 Gm.) of Dover's powder every three hours, beginning six hours after the administration of the first dose. After twenty-four hours the patient is given an alcohol rub, care being taken to have the room warm before exposing the patient. The bed sheets and the gown are changed, having previously been warned. The medication outlined above is continued for another twenty-four hours. No diet other than milk, with or without tea or whiskey, is given during that time.

The bowels should be looked after and a movement produced either by enema, by two fluid drachms (8 c.c.) aromatic fluid cascara, or by half an ounce (16 Gm.) magnesium sulphate well diluted with water (a glassful) and made palatable by the addition of some orange juice. It is essential that nauseating cathartics, such as castor oil, be avoided, inasmuch as the patient is frequently nauseated during an attack of influenza and because nausea and vomiting are not only physically and mentally distressing but also materially weaken the patient and call for an unusual and undesirable exertion of the circulatory and respiratory mechanisms.

Many cases of influenza proceed to uneventful recovery after the first 48 hours of above outlined régime. However, the physician should not be misled by the seeming well-feeling or good appearance of the patient at this stage and perchance make the grievous error of considering the patient out of danger. It is precisely at this time that care and caution are necessary. The patient should be kept in bed for at least seventy-two hours after temperature, pulse, and respiration have returned to normal. During that time special attention should be paid to the diet. Easily digested but nourishing food should be given in small quantities and at frequent intervals. Cereals with milk, to which a very small amount of cream may be added, should form the principal articles of diet. A little orange juice or the juice of grapefruit may be given, but not in conjunction with the meal. As a rule carbonated waters are best omitted because of the gastric distention following their administration. The pulse, usually slow and full, requires no medication but attention should be paid to the blood pressure. Many of of the cases showed a blood pressure of less than 120 mm. Hg. systolic, and between 60 and 70 mm. Hg. diastolic. In these cases we found it advantageous to administer three to five minims or drops of solution adrenalin 1:1000 every four to six hours. It is not necessary to inject this hypodermically. We can obtain equally good results by placing the drops underneath the tongue, near the ranula, and thus avoid inflicting pain on the patient.

If the temperature persists for three or four days after treatment has been initiated one may

*Read at the twentieth annual meeting of the American Therapeutic Society, at Atlantic City, N. J., June 6 and 7, 1919.

suspect pulmonary involvement even in the absence of demonstrable or discernible physical signs. Our rule was to consider such cases potential pneumonia cases, presumably of the bronchopneumonia type and to treat them accordingly. The Dover's powder and quinine powder were continued unless symptoms supervened which made such procedure contraindicated, such as ringing of the ears, marked restlessness, or nausea with or without vomiting. In such cases the quinine was omitted for twenty-four hours and recommenced with a smaller dose, if then tolerated. Râles or audible respiratory sounds called for application of hot flaxseed poultices, renewed every half hour. A rapid heart was controlled by early application of digitalis in the form of the tincture and in doses of 15 to 30 drops every three hours. This was replaced by 10 drops of adrenalin solution in cases where the digitalis was not well borne, as evidenced by nausea or vomiting. If the patient appeared at all toxic we administered 10 c.c. of a 10 per cent. solution of camphor in olive oil or in expressed oil of sweet almonds, twice a day, hypodermically.

The cough was treated according to the character of the expectoration. In cases showing a thick, tenaceous sputum the salts of ammonium, either the chloride in doses of two to three grains (0.13—02 Gm.) in plenty of water, or liquor ammonii anisati, minims 15 (1 c.c.) well diluted, or ammonium iodide five grains (0.3 Gm) in solution, were given at four-hour intervals. Any of the other ammonium salts may be used instead. In the cases, few and far between, showing abundant liquid and frothy expectoration codeine sulphate or phosphate, in doses of one-quarter of a grain (15 milligrammes) dissolved in water or syrup, was administered orally. At all times attention was paid to bowels and urine.

It is needless to add that pleuritic complications were treated in the usual manner, the dry type by hot applications (poultices preferably), or by strapping, those showing effusion, not rapidly yielding and keeping up a septic temperature, especially after a primary defervescence of temperature, were either aspirated or thoracotomy was resorted to. In cases of the latter type, which were handed over to the surgical division, the following procedure was tried with satisfactory results: Two aspirating needles were inserted; one of smaller caliber (about 20 bore) at the uppermost border of the area of flatness, the other of larger caliber (15 bore) at the lower border of flatness. As much as possible was aspirated through the lower needle, then the upper needle was connected with a transfusion apparatus containing physiological saline solution at body temperature and the pleura was irrigated until the return at the lower needle appeared free from purulent or fibrinous material.

One must bear in mind that the patients with whom we had to deal, with very few exceptions, were sent in after an indefinite period of illness at home. The homes from which they came belong to the poorest in the city and the preliminary treatment afforded them previous to admission was, as a rule, in accord with their environment. In the face of all these handicaps we felt that our mortality rate of a little less than 22 per cent. was a fair indorsement of the rationale of our treatment.

316 West Eighty-fourth Street.

THE GENERAL TREATMENT OF INFLUENZA.*

By NOBLE P. BARNES, M.D.,

WASHINGTON, D. C.

Specific therapy is always handicapped when specific etiology is clouded in mystery, consequently general management and symptomatic treatment become the most dependable aids the physician has in his combat with epidemic influenza.

The influenza bacillus has for several years been regarded as the "Arnold von Winkelried" of the bacterial world in breaking down the defences of the human body. This claim was accepted during the visitation of epidemic cerebrospinal meningitis a few years ago. Our recent plague, "the flu," following upon the heels of the pneumonia and empyema slaughter in our camps, might be regarded as a virulent combination of organisms, the influenza bacillus again illustrating the adage emphasized by goodly books and Godly people that "evil communications corrupt good morals." Whatever morals this vacillating influenza bacillus has, its relation to the microscopical world is not unlike that of oxygen to the chemical world, where the gay Lothario mingles and unites with saint or sinner with equal alacrity, often to his own detriment, sometimes getting severely burned.

In respect to the bateriology of influenza, the work of Dufour[1] in cultivating on medium supplied with oxygen, a diplococcus taken from the blood of influenza patients, is equalled by the experimental research of Segale,[2] who claims his *Streptococcus pandemicus* cultivated from influenza cases, is something new, capable of passing through a Chamberland filter, and producing typical influenzal symptoms in guinea pigs. Hemorrhagic effusions in the peritoneum and lungs with congestion of the respiratory apparatus were observed in guinea pigs treated with the filtrate of this *Streptococcus pandemicus* that had been heated to 55° C. for an hour.

Gibson, Bowman, and Connor[3] have succeeded in growing a coccoid shaped, minute microorganism by Noguchi's cultural methods, from kidney, lung tissue, and filtered sputum of influenza cases. By direct cultures the microorganism has been carried to the third generation. Inoculated animals exhibited typical "experimental influenza" and cultures of the microorganism were again recovered from them. The pathological lesions in these animals closely resemble those seen in the lungs of men.

Rosenow[4] in his experimental work has discovered and cultured a green-producing streptococcus that he regards as having played an important rôle in our last epidemic. His most concise statement is, "the uniformity of symptoms in typical influenza suggests that the cause is a single bacterium having pandemic characteristics." He is of the opinion that a pandemic strain may be found belonging to the

*Read at the twentieth annual meeting of the American Therapeutic Society at Atlantic City, N. J., June 6 and 7, 1919.

green-producing streptococcus as shown by his immunologic studies.

All bacteriological reports emphasize the presence of types of pneumococcus and streptococcus in greater constancy than the *Bacillus influenzæ* or any other organism except the *Micrococcus catarrhalis*. All these organisms are now looked upon as playing a secondary rôle.

The recent epidemic is too fresh in the minds of medical men to require a rehearsal of the history, onset, symptoms, and course of this disease. The epidemic of 1889 and 1890, with an increased mortality due to the use of the new and then popular coal-tar derivatives, was mild in comparison. The chilly sensations, headache, malaise, and exhaustion of the epidemic of thirty years ago faded into littleness when compared with the chill and fever, sudden prostration, cyanosis, extreme toxemia, and typhoidal state of the latest scourge.

To me one of the most constant physical signs in our recent epidemic was obtained by auscultation, by the employment of the expiratory cough. With the patient's arms drawn across the chest and the examiner's ear placed over the inner border of the scapula, a shower of fine, sticky, crackling râles was heard, usually more pronounced on the right side. The pharynx was generally reddened, sometimes intensely red and swollen. The tonsils were rarely affected.

In some severe and fatal cases there was the usual break in the temperature, a remission or an intermission, followed by a chill and sharp rise of fever often associated with hemoptysis, occasionally with epistaxis, and an atypical pneumonia rapidly spreading from hemorrhagic spots in the posterior basal lobes of the lungs. These spots, which I have spoken of as hemorrhagic splashes, are in fact hemorrhagic pulmonary edemas, the progress of which can be followed by radiograms.

The postmortem findings, as a rule, parallel the physical signs. The lower part of the larynx, the trachea and the main bronchi are red, swollen, and covered with a yellowish-gray deposit under which are small hemorrhages. The smaller bronchi are sometimes filled with a red foam. The peribronchial lymph nodes are enlarged, red, and soft. The posterior portion of the lungs is dark red and uniformly firm, due to the deposit of blood; the anterior part, especially of the middle and upper lobes, is gray or pink elastic and contains air. On section of the consolidated portion of the lungs large quantities of bloody fluid exude. Changes in the heart and pericardium are not noted and only changes usually associated with the toxemia of severe infections are noted in the abdominal viscera.

The annals of influenza, dealing with the epidemics of the sixteenth and seventeenth centuries, published by the society perpetuating the name of the great clinical observer, Sydenham, illustrate the tendency of this disease, uncomplicated, to run a typical course to a rather prompt recovery with, without, or in spite of treatment for the purging, blistering, and bleeding employed in those days could not account for the low mortality.

Prophylaxis here, as in most other diseases is of greatest importance. Recognizing the rapid spread of the disease, every case and every suspect should be isolated and screened and every hygienic precaution should be taken. Coughs and sneezes must be caught in gauze masks, in handkerchiefs, or in napkins sufficiently large to cover the face. The attendants should wear masks and observe the strictest personal cleanliness in order to protect themselves. They should also receive immunizing vaccines. Persons at large, sneezing and coughing, should be treated as a dangerous menace to the community, properly fined, imprisoned, and compelled to wear masks until they are educated out of that "Gesundheit," "God bless you" rot. This is certainly better than compelling the whole populace to wear masks, which is about on a par with asking people to wear shinguards during "dog days." Every rational control method should be employed to stay the spread of the epidemic even if these mean only dragging the plague over a longer period of time.

The patient's room should be light, airy, and free from dust; the windows should be open and screened with gauze, and the passages from the room should be protected by sheets kept moist with an antiseptic solution. Disinfection of linen, eating utensils, floor, and walls should be the same as that employed in scarlet fever. Sputum cups, paper napkins, and paper bags for holding soiled napkins should be at hand.

Portable bedside roentgen-ray machines are valuable aids for following the course of the disease, also blood-pressure apparatus for checking up the strength of the heart. After a diagnosis is made, frequent physical examinations should be avoided, as they aggravate a condition in the lungs that should be kept at rest.

Bacterial filtrate prepared from organisms commonly present in influenza or immunizing vaccines for anticipated complications should be used to increase natural resistance, as this disease seemingly fails to awaken the body's defensive forces as is shown by leucopenia, asthenia, vasodilatation, and hemorrhagic tendency.

Nonspecific protein treatment has given some striking results and evidently has a definite therapeutic value. Cowie and Beaven[6] in their discourse on the use of typhoid protein give the following conclusions: "An intravenous injection of typhoid protein in influenzal pneumonia is a safe procedure within limitations. Intravenous injection of typhoid protein is indicated only in the beginning stage of the pneumonia, so far as we are able to determine from our limited number of cases. The use of this method of treatment is contraindicated (*a*) in cases of influenzal pneumonia advanced beyond the third day of the disease, or (*b*) when there is undoubted evidence of advanced myocardial insufficiency or acute endocarditis. No more than five hundred million dead typhoid bacilli should be given at one injection. For well-known reasons, at least forty-eight hours should intervene before another injection is given. The immediate effect of the foreign protein is the development of a typical protein paroxysm, which is followed by a marked decrease in the temperature and a definite improvement in the subjective symptoms, both of which are usually permanent. Following the injection of the typhoid protein, there is a characteristic leucocytic movement. The leucocyte increase in the cases studied is only of moderate degree. There is no permanent improvement in the leucopenia or downward ten-

dency of the leucocytes. The effect on the pulse, respiration, physical signs, and urine findings is practically negligible. An intravenous injection of typhoid protein may bring about a termination of the acute symptoms of the disease in from one to three days."

Lusk and Brumbaugh[6] conclude their discussion on foreign protein therapy with the following, "Many cases, which appeared at their onset to be of the malignant type, would after its use show an improvement (often unexpected), with subsequent recovery. No improvement resulted unless a reaction occurred. For this reason we were partial to the more concentrated products (diphtheria serum and bacterial filtrate). The same benefit was derived from the antimeningococcic, antitetanic, and antidiphtheritic as from the antipneumococcic serum, provided a satisfactory general reaction resulted. In other words, there was no apparent specific action of any type of serum, but the result was dependent entirely on its protein content. Early administration was essential to effectiveness. No harm, attributable to their use, was ever observed. From the use of the serum there seemed to be a lessening of the hemorrhagic tendency. While an artificial crisis was desired and anticipated, more often, when benefit did result, it came as a gradual reduction in toxemia, in temperature, and in respiration. Of these products the bacterial filtrate was unquestionably the most satisfactory. Its concentration, the sharp reaction produced, the ease of administration (from 0.5 to 1 c.c. intravenously being used as an initial dose), and the absence of disagreeable urticarial or arthritic sequelæ, all being in its favor.

The work on protein therapy is in its infancy and gives promise in many conditions. The most desirable kind of protein is yet to be determined as well as the dosage, which in some instances is so small as to put passive immunity out of consideration. Foreign protein intravenous injections are less certain and require more care than bacterial vaccines. The latter are safe, convenient, and always available and a protein reaction can be secured by administering subcutaneously or intramuscularly a larger than treatment dose. They have the advantage of not producing anaphylactic sensitization so common with many foreign proteins.

Realizing the possibility of every case of influenza being or becoming severe, the patient should be put to bed with the first symptom and kept there until his evening temperature has been normal for four days, being permitted to get up at that time if the heart and lungs are normal.

Whatever the temperature of the room may be, the patient's body must be kept warm, and chilling of the surface or coldness of the extremities must be avoided. McGuire[7] gives an interesting account of his experience at Camp Wheeler. Nine hundred and ninety-six patients (Group I) treated by the cold air method showed a mortality of 13.9 per cent. Four hundred and thirty-five patients (Group II) treated by the no-chilling method showed a mortality of 3.2 per cent. While a diminished virulence of organisms or a higher resistance of soldiers may in part explain the lowered mortality in Group II, the difference in the mortality rate between the two groups is so pronounced that it seems reasonable to conclude that the no-chilling form of management employed in treating the Group II patients assisted in decreasing the mortality.

Diet should be to full digestive capacity, which means very little in some cases. Hot liquids—as lemon or orangeade, or a hot saline laxative, if needed—should be given as soon as the patient is put to bed. If the stomach is retaining fluids, water should be given freely; if vomiting is present, and persistent, and the tissues are depleted, tap water by the Murphy drip, after bowel washing, is useful in diluting and eliminating toxins. The foods that can be taken should be nourishing and easily digested. Where food is resisted, and especially in children, pure candy furnishes enough energy to bridge over a starvation period.

The drug treatment of influenza is largely symptomatic; this meeting of indications when they arise is in many instances the real test of therapeutic skill. There has been only one drug offered as a specific. Orlando[8] urges the use of phenol, stating that if this drug is employed we will behold "a mild course of the epidemic and no mortality." The best results, he claims, were obtained by intravenous injection. He also claims the kidneys not only did not suffer, but preexisting albuminuria sometimes cleared up. This method of treatment cannot be regarded as rational.

Small and Blanchard[9] report a study of groups of patients, fifteen in each, placed on different drugs. The progress of the various groups was noted and compared. "Aconite, acetylsalicylic acid, sodium salicylate, belladonna, arsenic, quinine, Dover's powder, and gelsemium were tested in this way. The patients treated by gelsemium improved in a manner far exceeding those given any other treatment. After a few doses, headache and backache had been much relieved, and the patients felt greatly benefited in every way. In most patients the temperature speedily commenced to fall, and the improvement in the general condition was obvious. Of the other drugs tested, belladonna showed evidence of beneficial action in a number of cases, but none of the other drugs appeared to have the slightest influence. The patients were not selected in any way, but were taken consecutively as they were admitted."

The initial symptoms are usually well met with the old-fashioned pulvis ipecacuanhæ et opii. The cough, the pain, the restlessness, if present, are thus releived, and the fever and circulatory unbalance benefited by the diaphoresis. Codeine or heroine and ammonium salicylate may be substituted. Calomel and phenolphthalein or sodium phosphate do all that castor oil will do, and are not so illy received by the stomach. The belladonna group comes in for recommendation in dyspnea and cyanosis, and gives better results than most of the other drugs used to combat these symptoms. Inhalation of oxygen passed through warm alcohol gives relief. Digitalis, strychnine, caffeine, camphor, and whiskey have their advocates in combating the circulatory failure, but in this last epidemic I am free to admit that I was disappointed in their action. Pituitrin, especially for abdominal distention, has proven of value. Sodium veronal or sodium bromide are the hypnotics of choice. Calcium iodide in small doses has decided advantages over the so-called stimulating and

nauseating expectorants. Hexamethylenamine should be given at intervals or continuously in small doses.

The fever in uncomplicated cases seldom needs attention. The elevation may be sharp, but the duration is short, and we are coming to look upon this symptom as did Sydenham when he observed, over two hundred and fifty years ago, that "fever is nature's engine to burn up infection." Hyperpyrexia can be met by hydrotherapy, which likewise relieves the nervous symptoms. Precautions against chilling the surface of the body and cooling the extremities should always be observed.

Local medication is useful, and may be summarized as follows: Boric acid or argyrol, in aqueous solutions, for eyes and nose. Sodium chloride and bicarbonate, in aqueous solution, for nose and throat wash. Tincture of benzoin compound in vapor inhalations, or 2 per cent. menthol and chloretone in liquid petroleatum by nebulizer for irritations of the air passages. Counterirritants, as equal parts of olive, amber, and clove oils, are indicated for chest and back pains, and menthol preparations for head and neck pains.

The various types of the disease depend upon the location of toxins and accompanying inflammations. From otitis media and mania to gastroenteritis and arthritis the treatment should be to meet the indications as they arise, and never lose sight of the patient in the endeavor to eradicate the disease and its complications.

A few negative phases in the treatment are equally important. Don't allow your patients to regard drugs and disease so lightly as to be constantly prescribing for themselves. Don't allow them to be misled by the usual idiotic treatment appearing in the press, which is generally to advertise somebody or something. Don't allow them to use strong and irritating gargles that remove the protecting mucus and leave a reddened and unprotected membrane. Cold water gargles are better. Teach them to treat the mucous membranes kindly. Don't allow them to walk around with a fever; put them to bed and don't allow them to get from under the covers until the danger from their infection is past. Don't give coal-tar derivatives or other depressing drugs; the disease is depressing enough without adding this therapeutic insult.

Regardless of any therapy instituted in the treatment of those stricken with influenza of the type we experienced during the past year, the one essential measure is rest, absolute, prolonged rest in bed.

THE CONTROL OF EPIDEMIC INFLUENZA IN A LARGE INSTITUTION.*

By HORATIO C. WOOD, JR.

PHILADELPHIA, PA.

PROFESSOR OF PHARMACOLOGY AND THERAPEUTICS IN THE UNIVERSITY OF PENNSYLVANIA.

In these days of microscope and *x*-ray, one hardly dares to believe in the existence of things seen with the unaided eye; but as the labors of the bacteriologist, pathologist, and chemist have so signally failed in promoting our knowledge of either the cause or treatment of epidemic influenza I have summoned courage to recount a purely clinical observation, the results of which seem at least suggestive of how this scourge may successfully be dealt with.

In order that the measures employed at the University of Pennsylvania may be intelligible, let me first briefly describe the conditions at that institution at the time of the epidemic, and then tell what was done and the results achieved.

We had at the University of Pennsylvania one of the largest, if not the largest, units of the Students' Army Training Corps in the eastern United States, numbering when complete approximately twenty-five hundred men. At the time the epidemic struck Philadelphia, the organization of this unit had scarcely begun; only a handful of men had been admitted to the corps, and there were but two officers and no physician attached to the unit.

The University of Pennsylvania is situated in a densely populated section of Philadelphia, and we have a large number of students living in various parts of the city who go back and forth to their homes daily. The dormitories, which were used by the military authorities as barracks, consist of a large number of small houses built around the sides of a large open campus or courtyard. Each house is three stories in height, and there are from four to six rooms on each floor. Besides the dormitory buildings, several fraternity houses were also used as barracks; and two of the latter were used as an emergency hospital during the epidemic. At the beginning of our work there were perhaps three or four hundred men sleeping in the dormitories—the majority of the students not yet being admitted to the corps were living in boarding houses in the neighborhood—and there were already some sixty or more known cases of influenza among the students living in the neighborhood of the university.

I will not take up your time describing the difficulties met by the medical officers—only one of whom had ever had any previous military experience—in organizing the medical service for a corps of this size, while making as high as three hundred physical examinations a day of recruits and at the same time fighting the most frightful epidemic that ever occurred in Philadelphia, equipping completely and running an emergency influenza hospital for which neither nurses nor orderlies were available, and all this with a staff insufficient for a post of such size in ordinary times.

The medical staff of the unit as eventually organized consisted of Dr. John W. Hunter, who acted

*Read at the Twentieth Annual Meeting of the American Therapeutic Society, at Atlantic City, June 6 and 7, 1919.

as physician to our emergency hospital, and had oversight of the actual treatment of the sick; Dr. Frank B. Hancock, who was in charge of the sanitation of the barracks, and also of the physical examination of recruits; and myself as executive officer of the staff. Besides these, several of the internes from the University Hospital gave as much time as could be spared from their routine duties, and were of material assistance in many directions.

On account of the ubiquity of the epidemic it was impossible to obtain for our hospital either nurses or servants. For nursing we relied entirely on medical students. As soon as the seriousness of the situation was realized the commanding officer of the corps stopped all teaching for the third and fourth year medical classes in order that the students might be free to aid in the fight. I must confess that I was astonished at both the skill and the devotion of these young men. Called to do work of which they had no practical knowledge, at considerable personal risk they gave themselves wholeheartedly and uncomplainingly to the duty before them. Not only did they carry out faithfully the orders of the physician, watching most carefully the progress of each patient, and reporting intelligently and promptly any alarming change, but, what surprised me especially, they showed both cheerfulness and carefulness in cleaning bedrooms, mopping floors, emptying bedpans, washing dishes, and performing similar important but uninteresting tasks.

The measures employed in fighting the scourge may be conveniently divided into those intended to prevent the spread of the infection and those employed in treating the already sick.

Prophylaxis.—As already mentioned, the efforts directed toward stamping out the influenza conflagration before the whole university should be involved were under the immediate supervision of Dr. Frank B. Hancock. His selection for this task was peculiarly fortunate, not only because of his untiring energy, but because of his previous experience fighting infectious diseases during his service as naval surgeon some years ago.

Our first efforts were directed toward cleaning up the dormitory and college buildings, for while we realized that the boarding houses were fruitful sources of infection, they were not under military control, and the problem of how to deal with them was more complicated. We believed that the most important single factor in the spread of the disease was the infected individual, and consequently the most important prophylactic measure was his immediate detection and isolation. It will not suffice in so highly contagious a disease to wait until the man is sick enough to report for treatment, as there may be an interval of twenty-four or forty-eight hours during which he can infect half a dozen roommates. We therefore had daily rounds made of every room in the dormitory for the express purpose of discovering any case of any indisposition. When a sick man was found he was immediately sent to our hospital for diagnosis, and if suffering with influenza was held in the hospital. Later, when we had established regular sanitary inspection, these inspectors also ordered all suspicious cases to the hospital, so that we really had two searches daily.

Each case of influenza discovered was immediately reported to the sergeant in charge of the sanitary squad, who closed and locked the room until it was disinfected. The method of disinfecting these rooms was first to mop the walls and floor with a 1:1000 solution of corrosive sublimate; spray the furniture, walls, bedding, etc., with a formaldehyde solution, in such quantity that approximately one pint for each thousand cubic feet of air space was used; and close the room for twenty-four hours.

As much as has been written on the subject of droplet—that is, direct contact—infection, I am convinced that this is not the only mode of spreading the contagion. In an interesting paper in the *American Journal of Public Health* (January, 1919, page 25), Colonels Lynch and Cumming, as a result of their studies in several military camps, reached the conclusion that in the larger proportion of cases the infection was hand-borne, chiefly, they believed, from washing dishes in a common receptacle without boiling. The failure of face masks, either when employed wholesale, as in San Francisco, or in the thousands of individual cases throughout the country, is notorious, and would seem to argue in favor of the importance of the hands as a means of carrying the contagion. I may add that our experience in the hospital, as described below, also confirms this view. Believing strongly in this indirect contagion, we insisted not only on the immediate confiscation of all common drinking vessels and towels, but on the daily disinfection of all hand basins and toilets. In addition, the buildings were given a thorough cleaning, such as they had not had in many a day.

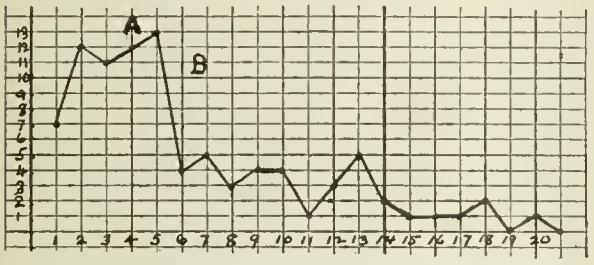
These measures were feasible in the dormitories by virtue of our military control of those buildings, but as soon as a portion of the limited force at our disposal could be spared from what we deemed the more pressing necessity we turned to the problem of the boarding houses in the immediate neighborhood. Two of the internes from the University Hospital, Doctors McMaster and Schmidt, made a map showing the location of every known case of influenza occurring near the university, whether treated at our own hospital, at the University Hospital, or by outside physicians. It was immediately evident that some of these boarding houses were hotbeds of infection. For instance, Dr. Schmidt reported one day on two houses as follows: "At —— Locust Street there were nine cases of influenza, four of whom have been admitted to the emergency hospital of the S. A. T. C. One went home and died of pneumonia, and the others have apparently recovered. At —— Walnut Street there are eight students, one of whom has been admitted to the emergency Hospital and the other seven have had mild symptoms."

While we had no formal authority over any of these boarding houses, nor over the students in them (as they had not at that time been inducted into the corps), we found, usually, that the boarding-house keepers were anxious to cooperate as soon as they were informed of the conditions, and we were allowed to disinfect the house; in the one instance where we encountered opposition we adopted the tactics of informing the other boarders of the situation, and the next day the landlady was begging for a squad of formalizers. It should be emphasized in this connection that the fumigation of bedrooms is not enough. The bathroom must be disinfected, and one must also descend into the

kitchen and see that the dishes are properly washed.

We did not believe that the classroom was a common source of trouble, and consequently all classes were allowed to continue as usual, except the two upper medical classes and the dental school. The medical class was closed because we wished to avail ourselves of the services of the students, the dental school house because the dental clinic was evidently fraught with extraordinary danger, both to the patient and to the student who treated him. Two other buildings were temporarily closed, namely, the swimming pool and the students' clubhouse, known as Houston Hall, where the students are wont to congregate during their leisure time.

The number of cases admitted to our influenza hospital—and it must be remembered that every sick student who had been inducted into the corps had to report at this hospital, and the great majority of the rest did so by preference—diminished so promptly and markedly after the institution of these measures that it is difficult to avoid the conclusion that there was more than an accidental connection between the two. The accompanying diagram shows graphically the daily admissions into the emergency hospital.



Curve showing daily admissions to emergency hospital. Figures on abscissa indicate days; figures on ordinate number of new admissions. At A began the daily search of dormitories for cases of influenza; at B began the cleaning and disinfection of the whole dormitories.

As shown in this diagram, within forty-eight hours of the beginning of our sanitary campaign there was a drop from an average of twelve to four admissions per day. This is all the more striking in view of the fact that at this time in the city at large the epidemic was increasing; it did not reach its zenith until the 12th or 13th of October, by which time we considered it practically stamped out at the university. It was due chiefly, I believe, to our sanitary measures that the total death rate at the university was only 1 per thousand of population, as compared with 8 per thousand in the rest of the city.

Treatment of the Sick.—Our therapeusis was very simple but, I believe, important. Every man was put to bed immediately and kept there, not being allowed to get up for any purpose so long as he was febrile. Our rule was to keep patients in the hospital until their temperatures had been normal for three days. At the end of this time they were sent to a convalescent house where they were kept for another week, reporting daily at the hospital for treatment.

Every patient received on admission a calomel purge and was placed on semiliquid diet during the febrile stage. He received from twenty to thirty grains of quinine and from twenty-five to forty grains of either strontium or phenyl salicylate daily. Very little other medicine was needed. Occasionally in cases with marked bronchial symptoms a few doses of a simple cough mixture, as ammonium chloride with Brown mixture, were ordered. Once in a while, when the headache and backache were more than ordinarily severe, a few small doses of acetanilide were given. In this connection I may express my conviction that aspirin is a much more dangerous and less efficient remedy for the relief of these pains than is acetanilide; personally I am of the opinion that the frightful mortality of influenza in the military camps was in part due to the freedom with which aspirin was used. Fever as such was never treated. In one or two cases ice bags were applied to the head for the purpose of relieving headache due to a high temperature; but I do not recall that we ever employed any antipyretic measure, either medicinal or hydrotherapeutic. A considerable number of our patients ran temperatures of 103° to 104° for a day or two but we soon ceased to be disquieted in any way by high temperatures. In only a few instances did we feel the need of any circulatory stimulant and in such cases we preferred digitalis or strychnine to alcohol. In view of some of the statements that have been made concerning the value of alcohol in influenza, I may say that we used in our emergency hospital during the three weeks of its existence a total of three ounces of whisky and no other form of alcoholic stimulant.

We treated in our emergency hospital a total of 88 patients and of these two developed pneumonia, one of whom died. Of course the number of cases is very small to draw any conclusions, but when we consider the mortality in other military camps, the difference seems almost too great to have been accidental. At Fort Riley (Stone and Swift, *Journal of the American Medical Association*, 1919, lxxii, page 487) seventeen per cent. of the cases developed pneumonia, of whom thirty-five per cent. died, a total mortality of 5.9 per cent. At Camp Pike (*Ibid*, page 556) there was 31 per cent. of pneumonia cases and a total mortality of 3.8 per cent.

At Camp Cody (*Ibid*, page 1056) there was 19 per cent. of pneumonia cases and a total mortality of 7.3 per cent. It cannot be claimed that the infection in Philadelphia was of a milder type than in other parts of the country, for at the League Island Navy Yard Hospital, which is a Government property immediately adjoining the city limits, there was 8 per cent. of deaths, and the Philadelphia Hospital for Contagious Diseases treated 117 sailors and marines of the Fourth Naval District with more than 15 per cent. of deaths. In the Philadelphia Hospital for the Insane 443 of the inmates developed influenza, with a mortality of 15 per cent.

Practically all of the deaths following influenza are due to pneumonia, and the striking fact about our results is not that we had 1 per cent. of deaths, but that we had only 2.3 per cent. of pneumonia. This I believe was due chiefly to three things: First, that the majority of our patients had separate rooms; second, to the use of quinine from the beginning of the infection; and third, that we did not use aspirin. In further support of my idea that

our treatment played some part in our results is the fact that one of our pneumonia cases (the one which proved fatal) was diagnosed as such within twenty-four hours of his admission.

I may at this place, although perhaps not strictly the logical one, refer to the measures adopted for the protection of our nurses in the hospital. As I have intimated above, I have little faith in the face-mask. In fact, I believe that the type usually employed (a piece of gauze held to the face by tape or string) is a menace rather than a help. Nevertheless, partly as an added precaution and partly as a concession to popular superstition, we provided our nurses with the only form of mask which I have seen that seems at all practical. This, which is probably familiar to the surgical members of the Society, is a light wire frame on the order of the Esmarch chloroform inhaler held in place by means of spectacle sides fitting back of the ears. In the frame we used a double thickness of surgical gauze soaked in a 1:1000 solution of mercury bichloride. The gauze was renewed daily. The men were also provided with surgical gowns which they wore in the sick-room. These were sterilized daily. Our main confidence, however, was placed in hand-washing. Every time the patient or anything pertaining to him was touched, the nurse immediately afterward, before doing anything else, washed his hands and rinsed them in antiseptic solution and dried them on paper towels.

Neither Dr. Hunter nor myself used face-masks or gowns, but relied solely on hand-washing to protect us, naturally, however, avoiding as far as possible getting in contact with the patient's breath. It is a record for which we are grateful that out of forty men coming in intimate contact with these patients, either as nurses or physicians, only one developed influenza.

Conclusions.—I am well aware that it is very dangerous reasoning to draw positive conclusions from an observation so limited as that here reported, but I think at least I am justified in saying that the following conclusions are suggested even if they are not proven:

1. That the most important prophylactic measure in combating epidemic influenza is the complete isolation of the patient; this should be done at the onset of symptoms and not wait until he is so sick that he takes to his bed of himself.

2. That the hands are an important means of conveyance of the infection and that no efforts at protection of the individual or limiting the spread of the disease which does not take into consideration the possibility of hand-borne infection is complete.

3. That proper isolation of the patient in influenza means not merely isolating him from healthy persons, but also from other cases of the same disease.

4. That quinine has value as a prophylactic against pneumonia. In support of this view I may also call attention to the work of Cohen and his collaborators (*Pennsylvania Medical Journal*, May, 1919, page 506) who found that if quinine was exhibited in appropriate doses the blood was rendered germicidal to pneumococci.

1905 Chestnut Street.

LIPOVACCINES.*

By A. PARKER HITCHENS, M.D.,

INDIANAPOLIS, INDIANA.

THE recent mobilization of large groups of men made possible an intensive study of prophylactic and remedial measures; observations were made and their results collected to an extent that could not have been equalled in years of patient work under ordinary circumstances.

These results have been nowhere more satisfactory than in the prevention of certain of the infectious diseases, notably typhoid fever. Every one knows that if the incidence of this disease had equalled that of even so recent a time as the mobilization for the Spanish-American War, we should have had at least 200,000 cases in our hospitals, with many thousand deaths. As a matter of fact, according to the most recent statistics available,[1] from September 1, 1917, to March 28, 1919, there had been in the whole United States Army but 196 deaths from typhoid and the paratyphoid fevers.

Furthermore, during the war an important improvement in the methods of inoculation against infections was introduced, and progress was made in studying its various phases. I refer to the substitution of oils for the salt solution used as the menstruum in the preparation of prophylactic vaccines.

The name "lipovaccine" given these bacterial suspensions has been the subject of some discussion. "Lipo" may suggest a relation to lipoids, especially since the part played by lipoids in immunological reactions has been so much discussed during the past few years. The prefix "lipo", however, was used by the French investigators to indicate that the bacterial bodies were suspended in oil instead of the usual saline solution.

History.—The war directed attention to the urgency for simplifying prophylactic vaccination since military expediency demands the elimination of every unnecessary delay in the mobilization and movement of troops. To this end, Widal and Salimbeni[2] observed the effects of a reduction in the number of typhoid injections with a corresponding increase in the size of doses; they recommended that the dose be increased so that the full amount of vaccine could be administered in two injections, and that in cases of emergency the full dose be given at a single injection. With such doses of saline vaccines the resultant reactions would at times be severe.

It seems now somewhat curious that no one had thought of using as a vehicle for the antigens a substance which would be absorbed slowly, thus reducing the initial reaction and continuing the immunizing effect over a longer period. Although oils of various kinds and containing various substances have been used therapeutically by subcutaneous injection for years, Le Moignic and Pinoy[3] were the first to report the preparation and study of oil suspensions of bacteria for specific prophylactic purposes. In their first attempt they used a mixture of liquid petrolatum and lanolin, but later adopted vegetable oils.

*Read at the twentieth annual meeting of the American Therapeutic Society, at Atlantic City, N. J., June 6 and 7, 1919.

Achard and Foix[4] almost simultaneously reported the results of similar work in which they used olive oil. In this country, Whitmore[6] and his coworkers at the Army Medical School undertook a serious study of lipovaccines, and were able to give the army during the period of the emergency the benefit of those important advantages which lipovaccines have over saline vaccines.

List of lipovaccines which have been prepared.—The work of Le Moignic and Pinoy[3] and of Achard and Foix[4] was chiefly with typhoid vaccine. More recently, mixed lipovaccines have been prepared for Levaditi[8] by Lemaire according to the method of Le Moignic. In addition to a streptococcus lipovaccine, two mixed vaccines were prepared, one containing the staphylococcus and streptococcus, and the other containing the staphylococcus, streptococcus, and bacillus of Friedlander. As an adjuvant to the treatment of infected war wounds these lipovaccines are said to have given excellent results.

Bossan and Le Moignic[7] have prepared lipotuberculins. They have used suspensions of the tubercle bacillus itself and the filtered products of the tubercle bacillus. They claim that these tuberculins are innocuous so far as local and general reactions are concerned, and constitute efficient antigens.

The work at the Army Medical School in Washington has greatly extended our knowledge with regard to the value not only of typhoid lipovaccine but likewise of several other oil suspensions. Much attention has been given to the pneumococcus lipovaccine concerning which Fennel[5] has recently reported. Under Whitmore, triple typhoid, pneumococcus, meningococcus, dysentery, cholera, plague, and influenza bacillus lipovaccines have been prepared.

It was my privilege, while stationed at the Army Medical School, to prepare the plague and influenza bacillus lipovaccines, and the method of preparation used for these is illustrative of the general technique worked out at the Army Medical School for lipovaccine production.

Preparation of lipovaccines.—Broth cultures and saline suspensions of bacteria from agar cultures are passed through a Sharples separator. The bacteria are thus thrown out of suspension and collected as a thick, pasty mass. This is transferred to Petri dishes and dried with the assistance of unslaked lime. When dry, definite weights of the desiccated bacteria are placed in heavy pyrex glass jars of about 5,000 c.c. capacity, together with steel balls such as are used in ball bearings. The jars are then revolved until the bacteria are reduced to a fine powder; this requires about 24 hours. To each jar is then added a mixture of lanolin and cottonseed oil, the amount of lanolin representing about 3 per cent. of the final volume. After mixing for from 8 to 12 hours, sterilized cottonseed oil is added up to the volume calculated from the weight of dried bacteria placed in the jar. There is also added with the lanolin mixture enough chlorbutanol to make 0.5 per cent. of the total volume.

After the final addition of the cottonseed oil the entire mixture is rotated in the grinding mill for from 8 to 24 hours. The lipovaccine is then ready for sterility and potency tests.

Sterility.—Problems connected with the sterilization of oils are not so simple as they might appear to those who have been accustomed to the sterilization of saline solutions and the ordinary culture media. It was pointed out a number of years ago by Novy that the layer of cream on the surface of milk had the property of protecting bacteria against the action of heat so that they could resist relatively high temperatures. It has been found by others that spores in oil are extremely resistant to heat. Even if a degree of heat should be found which would always kill every spore, this temperature probably would, as Le Moignic and Pinoy[3] found with olive oil, cause decomposition; these authors found that olive oil heated high enough to sterilize it sometimes caused abscess upon injection. Whitmore was apparently successful in sterilizing oil by the use of ultraviolet rays. For this purpose a very clear oil is necessary. It is obvious, however, that ultraviolet rays are not applicable to lanolin, and some other method than heat must be devised for the sterilization of those lots which are found to contain heat-resistant spores.

The problem of finding a disinfectant which, when added to the oil, will retain indefinitely its germicidal or antiseptic effect, also demands study. One way out of this difficulty is, of course, the preparation of sterile lipovaccines without the use of an antiseptic, and it is not unlikely that this procedure may be adopted.

Tests for Sterility.—In testing oils for sterility, account must be taken of the fact that bacterial spores may be so surrounded by a film of oil that the culture medium to which the oil is planted may not reach the spore. Obviously, a sterility test technique which did not successfully remove this envelope would not be adequate.

A method used at the Army Medical School was to place a small quantity of the lipovaccine in a glass-stoppered bottle containing bouillon and glass beads. After vigorous shaking the bottle was incubated and subcultures made at the end of 24 and 48 hours. The efficiency of this method depends, of course, upon how vigorously the bottle is shaken and how thoroughly the oil is emulsified.

Another method which has been suggested is to centrifuge the lipovaccine at very high speed and make cultures from the sediment.

Any such method would seem to be made more searching if the shaking and the centrifuging were carried out at a temperature of about 50° C., thus reducing the viscosity of the oil without destroying the living bacteria which might be present.

*Tests for Potency.**—We must not make the too common error of confusing tests for potency with tests for identity. Estimation of the antibodies produced in animals injected with a vaccine is a test for identity only. The ability of a vaccine to produce agglutinins and serums which will give positive complement fixation tests is not necessarily correlated with its potency for protection against the specific infection. Animal protection tests give us positive evidence, but they are at present applicable in few cases. The final test of activity is, of course, obtained by actual trial. In the absence of satisfactory tests for potency, it seems necessary to fall back on identity tests for control work; unfortunately, such tests may be misleading.

*In this section free use is made of the published work upon lipovaccines from the Army Medical School.

Triple Typhoid Lipovaccine.—Rabbits injected with a single dose of triple typhoid lipovaccine gave an agglutinin titer even higher than that obtained by the injection of the usual three doses of saline vaccine.[8] Young guinea pigs injected with 1 c.c. of the vaccine showed resistance to living cultures injected 10 days later. These results have been confirmed by Abe.[9]

Dysentery Lipovaccine.—Rabbits were injected with dysentery lipovaccine. Later their serum was found to contain specific agglutinins in relatively high titer.

Plague Lipovaccine.—The agglutinin titer of the blood of rabbits injected with plague lipovaccine was 1:40—in one case it rose to 1:80. This is not high, but it is sufficient to indicate that the vaccine has a specific effect when injected into rabbits. There has been no opportunity yet to test its value in man.

Meningococcus Lipovaccine.—A series of rabbits injected with the meningococcus lipovaccine showed variable results. Strains 1, 10, 30, and 60 were used. "With two exceptions, all show decided agglutination for strain 10, several for strain 30, the majority for strain 60, some in a dilution of 1:200. Only one of this series showed agglutination for strain 1 (1:25 dilution)."

Pneumococcus Lipovaccine.—In the case of the triple pneumococcus vaccine it was rather expected that we should be able to make a satisfactorp potency test by the immunization of mice, since the protection test for Type I antipneumococcus serum is, with reservations, so satisfactory. This hope has so far not been realized. The results reported by Whitmore, Fennel, and Peterson[5] show inoculated mice living after having received doses which were fatal to the controls.

In our own work we injected mice with 0.5 c.c. of the lipovaccine subcutaneously; after 5 and 10 days three of them were injected with one m.l.d. (minimum lethal dose) of living Type I culture; after 20 days three were given one m.l.d. and three 10 m.l.d. All the mice died in about the same number of hours as the controls. In the case of the 20-day mice those receiving one m.l.d. died before the controls.

So far too little work has been done upon lipovaccines to have developed satisfactory laboratory tests for their potency and in the case of some of them tests for identity are not highly satisfactory.

Superiority of Lipovaccines for Prophylaxis.—Single Dose: To the military authorities the unhampered movement of troops is the thing of greatest importance, and the difference between a single dose vaccine and one which requires at least ten days is enormous. This one factor therefore justifies a preference for the lipovaccine.

In civil life, one reason prophylactic vaccination has not been more popular is the fact that three injections are necessary. Every physician has had the experience of persons refusing to return for second and third doses. A lipovaccine, therefore, should make typhoid prophylaxis more popular among civilians and hasten the day when, in combination with sanitary measures, typhoid fever shall be eliminated.

The single dose prophylaxis will stimulate the wider use of vaccines for other infections. There was good reason for hesitation on the part of the army when it was suggested that troops be immunized against not only typhoid fever but also against pneumonia, cerebrospinal fever, dysentery, and cholera—to say nothing of the influenza complications.

Increased Dosage: The number of bacteria required for the satisfactory prophylaxis of typhoid fever was worked out thoroughly by Colonel Russell. In the preparation of the typhoid lipovaccine, therefore, the total number of bacteria contained in the three doses of the saline vaccine were consolidated into a single dose. This dose has been satisfactory in practical work.

No other prophylactic vaccine has been studied with the same thoroughness, and the necessary dosage was a matter of uncertainty. There was, furthermore, the feeling that results were not always satisfactory and immunity was of relatively short duration because the dosage was too low. The immunity following the use of pneumococcus saline vaccines in South Africa by Lister[10] seemed to disappear after three months. It seemed advisable to Whitmore to attempt the use of larger doses than the severe reactions would permit giving in saline suspension. It was found entirely practical to use a dose of pneumococcus lipovaccine containing 30,000 million pneumococci suspended in oil; *i.c.* 10,000 million of each of the fixed types—Lister's maximum doses were 6,000 million of each type.

We have no extensive reports concerning the practical value of meningococcus saline vaccine. The work of Gates[11] in which 3,700 soldiers were vaccinated gave some indication of its value. It is noteworthy, however, that even those men who had received the largest doses (Group VI, 200, 5-6,000, and 10,000 million) failed to show agglutination at 1-10, while among those injected with meningococcus lipovaccine at the Army Medical School some men showed agglutinins in high dilution—the response, however, was irregular. Two groups of men received at a single dose 10,000 million of each of the four types and a third group twice this amount.

In the experimental lots of influenza bacillus vaccine we made at the Army Medical School, 1 c.c. contained approximately 100,000 million bacilli. The plague lipovaccine contained 10,000 million, but observations made following its injection led us to believe it could have been much stronger without causing severe reactions.

Various observers (Hitchens and Hansen,[12] Smith,[13] Castellani[14]) have noted the fact that when several antigenic substances are injected together the tissues react to each individually; one antigen does not interfere with another. With the large doses possible in oil suspensions the prophylaxis of infectious diseases may be further simplified, within reasonable limits, by combinations similar to the triple typhoid and the triple pneumococcus vaccines.

Relatively Mild Reaction: In the preparation of the lipovaccine it is customary to use a small percentage of lanolin whose content in cholesterol is believed to neutralize the lipotropic toxic substances resulting from the splitting of bacterial proteins. This is one of the reasons such enormous doses of bacteria can be administered when suspended in the oil mixture.

The detoxicating effect of the lanolin is not per-

fect, however; there is always an initial period of intoxication following the injection of lipovaccine. While this reaction is usually mild, at times scarcely noticeable, it may be severe. It may come on within a very few hours, but rarely lasts beyond 24 or 48 hours, and it depends largely on individual susceptibility, the same lot causing all degrees of reaction when a large number of people are injected. This reaction is undoubtedly due in part to the peptones and amino acids derived from the culture media.

This applies, of course, to subcutaneous injection. Lipo vaccines should never be injected otherwise. Intramuscular injections are not only likely to be followed by severe reactions but there is theoretically a danger of fat embolism—the latter is probably remote, however.

Slow Absorption, Resulting in Prolongation of the Immunizing Process: When a saline suspension is injected its entire bacterial content comes rapidly into contact with the tissues and the resulting train of events begins and ends as a single wave with a narrow apex.

In the case of the lipovaccine, absorption is slow and the stimulation received by the tissues continues for a considerable period. Thus, the latter more closely simulates the establishment of immunity by the disease itself, or the immunity obtained through the use of living vaccines.

This time factor is immunologically the most important point in favor of lipovaccines. Therefore, to be most effective the oil suspension should be about what we understand by "a perfect emulsion". That is, the bacteria should not settle out of the suspension even after standing at rest for a considerable time and after injection the last particles of oil absorbed should still contain bacteria in suspension.

The lipovaccines I have seen so far would not meet this requirement. The oil removed from its pocket in the subcutaneous tissues of an injected animal is found within a few days after the injection to be perfectly clear, and no bacteria can be detected by the microscope. The immunizing process does not, of course, continue throughout the period of absorption of the oil in the case of such vaccines. There is here, therefore, room for improvement and an indication that we shall eventually have a product more efficient even than that which has demonstrated its superiority over the saline vaccines. One of the criteria of efficiency of lipovaccines for the future should be a minimum length of time during which the bacteria must be held in suspension.*

Permanence of the Lipovaccines: Saline vaccines probably lose their potency through hydrolysis of their bacterial protein; this is hastened in some cases by the enzymes of the bacteria themselves. An essential to the hydrolytic change is the presence of water. Lipovaccines made with dry oils and containing dried bacteria should therefore remain permanent for an indefinite number of years. This is a point of great economic importance. It is now the custom to withdraw from the market all saline vaccines beyond a certain age and replace them with fresh products; much of the increased cost of producing the lipovaccines will thus be neutralized.

Uniform Dosage: A final advantage lies in the fact that in the case of the lipovaccines the dried bacterial masses are weighed and the vaccines are made up to contain a certain weight of bacteria per cubic centimeter. This is obviously a great advantage over the admittedly inaccurate methods of estimating by turbidity, and of counting which are used in the preparation of the saline vaccines.

Prophylactic Use of Lipovaccines in Man.—Only two of the lipovaccines have been used extensively for prophylactic purposes in man. (The streptococcus and mixed vaccines prepared for Levaditi were used only therapeutically.) These two vaccines are the typhoid and the pneumococcus.

Statistics with regard to the value of the triple typhoid lipovaccine in comparison with the saline vaccine are not yet available. There were a few small localized epidemics of typhoid in the army due to a variety of causes which in no way diminish our confidence in the triple typhoid vaccine. The earlier of these epidemics at least were in men who had received only saline vaccine and there seems little doubt that the triple typhoid lipovaccine was at least equal in value to the saline vaccine. The figures given by Billings, which are noted above, make further comment unnecessary.

Pneumococcus lipovaccine was used at Camp Wheeler by Cecil and Vaughan[15]. They immunized about 80 per cent. of the entire command. A large number of these troops were new recruits who, as Opie[16], has noted are more susceptible to respiratory infections than are seasoned troops; in addition to this the epidemic of influenza complicated the situation. And, again, the work was interfered with by the commencement of demobilization in spite of which, however, the period of observation extended over a period of three months.

About the same number of cases of pneumonia of all types occurred among the 20 per cent. of the command which had not been vaccinated as occurred among the 80 per cent. of troops who had been vaccinated; that is, 363 among the vaccinated and 327 among the unvaccinated. At the same rate there should have been four times this number or 1308 among the vaccinated. Excluding cases that developed within one week after the inoculation, that is before protection could be expected to have developed only 8 cases of Types I, II, and III pneumonia developed among the vaccinated men, and these were all secondary to severe attacks of influenza.

Conclusions.—The development of lipovaccines constitutes an important advance in the means by which infectious diseases may be prevented.

Oil vaccines to be of greatest value should be permanent suspensions.

Since such vaccines make it possible to administer relatively enormous doses without severe reactions it is possible to immunize against infections by the injection of a single dose.

*Subsequent observations have shown that while the bacteria in oily suspension may settle out more or less rapidly upon standing due to ordinary sedimentation, other factors are brought into play after injection. When suspensions of bacteria in oil are brought into contact with other immiscible fluids the bacteria settle out rapidly and collect in a layer within the oil but just above the other fluid. After injection into the tissues the thin layer of oil probably loses its bacteria within a very short time.

Such vaccines do not undergo rapid deterioration and their content in bacterial protein may be accurately standardized.

Methods for preserving them against contamination, and for examining them for sterility and potency, are still under investigation.

The record they have made already in the prevention of the typhoid fevers and the infections caused by the fixed types of the pneumococcus demands that the essential work yet undone be expedited as much as possible.

INFLUENZA IN THE MILITARY CAMPS.*

By LT. COLONEL THOMAS W. JACKSON, M.D.,

PHILADELPHIA, PA.

ASSISTANT TO COMMISSIONER OF HEALTH OF PENNSYLVANIA

I FIND it easy to agree with almost, if not quite, all that Dr. Stewart has said in his historical résumé, and if I hold slightly different opinions or impressions in certain matters touching the bacteriology of influenza the fact is not important, nor do I propose to enter into any bacteriological discussion at this time.

This general statement is true that during the recent influenza epidemic in the great army camps no adequate or well controlled test of vaccination was undertaken or carried out. Therefore no conclusions based on large army experience, prior to or even during the early days of extensive epidemic appearance of the disease, are justified. Naturally, all measures undertaken after the peak of the epidemic incidence curve is passed are subject to grave question when it comes to judging their effects.

In the May number of *Modern Medicine* the editor of that journal, speaking of our unpreparedness for the recent influenza epidemic, refers more particularly to civilian communities, but his remarks also have a certain applicability to the military establishment as it existed in the United States in the autumn of 1918. He says:

> We were quite unprepared when the epidemic of influenza broke upon us in all its fury. Our hospital and nursing facilities were at once taxed beyond capacity, and methods of prophylaxis were, as a general rule, organized only after the disease reached a community and not before. Our research laboratories, for the most part, got under way their investigations after the epidemic had well nigh run its course. Even the technique of culturing the influenza bacillus had to be learned anew and the difficulties mastered. When at last the workers had become oriented and had their plans made for investigations along new lines and with more modern methods, the opportunity was gone—the epidemic had passed. The clinicians were equally unprepared. An appreciation of the fatality of the pneumonia, . . . the futility of the usual drug therapy, including that of the coal tar products, all had to be relearned.

It is true that a Division of Epidemiology had been created in the Surgeon General's office during the previous winter and that perhaps a dozen or fifteen qualified men had experienced nearly a solid year of intimate study of the epidemic respiratory infections, as they occurred in the camps and cantonments, epidemics taking heavy toll of life and seriously interfering with military mobilization and the training program.

As one of these epidemiologists, it was my exclusive duty to carry on resident study of these respiratory disease epidemics, notably measles, pneumonia, and influenza, in three camps. viz., Camp Bowie, Texas; Camp Custer, Michigan, and Camp Meade, Maryland, widely separated military communities made up of individuals from geographical sections representing extremes of latitude and including both white and colored troops—more than 100,000 men in all. The functions of the epidemiologists were advisory, and in no sense mandatory, and often military necessity, or what was deemed military necessity, prevented the putting into effect of certain of the epidemiologist's recommendations, even when approved by the Surgeon General's office.

Perhaps I cannot use a part of my time better than in calling attention to the fact that in contrast with the prevalence of influenza in civil communities, dreadful as it was, the epidemic expression of the disease in the military camps which it invaded was many fold worse; so bad, indeed, that there is no general realization of the difference. Proportionately, more of our troops in the United States—the flower of our young manhood—succumbed to influenza and its dread accompaniments than to German bullets, shells, bombs, and torpedoes in Europe or on the seas. Had you seen what I have seen, and walked as I have walked, down long rooms where hundreds of dead men, your comrades of a day or so before, were aligned in military ranks, recumbent on the floors, awaiting unobtainable coffins for burial, you would appreciate this fact.

It cannot be said of these men that they died unwept, but they have been practically unsung, and I bespeak for these thousands a thought of thankful remembrance—for they, too, died for our country.

The statistics I am going to give you relate to Camp Meade and have never been published. They are accurate. They correspond in a notable way with those of several other camps of similar size.

*Remarks in opening discussion on influenza before the American Therapeutic Society, at Atlantic City, June 7, 1919.

There is no reason why they should be unrecited. Their recital involves no shadow of criticism of the Government or the profession, for the country and the world acknowledges defeat at the hands of the recent epidemic enemy.

In the face of these statistics and the fact that nearly 2 per cent. of our command died in bed in the period of a month, we cannot point with satisfaction or confidence to the efficacy of any control or repressive measure applied—sanitary, medical, quarantine, or restrictive. It appears that the epidemic spent its force unchecked and reached its end chiefly through the exhaustion of susceptible human material.

If like conditions prevailed in civil communities among the young men of the country, the casualties of war, spread over many months, would appear insignificant beside the toll from a single month of epidemic disease.

From the mass of bacteriological data collected during pneumonia epidemics in the past year we have naturally expected that there would emerge some conclusive thought or agreement as to the etiology of the pneumonias, but as yet this expectation has not been realized because of diverse results, the personal equation and, perhaps, the personal viewpoint among laboratory workers. At any rate, there has been no such crystallization of opinion as to fix upon a single organism or a single group the cause of pneumonia. Indeed, the trend of thought seems to be away from such an opinion and toward the view that numerous pathogenic bacteria may cause pneumonia. We may very safely assert that there are numerous bacteria which, alone, or in combination, produce pneumonia.

In combating pneumonia and influenza we are left, therefore, to the necessity of making warfare against a group of possible causes and causal factors. In many of the other dangerous epidemic diseases we have definite points of attack. To overcome malaria and yellow fever, to prevent plague and typhus, we need only destroy the insect vectors. In smallpox, typhoid fever, and diphtheria we command control which is practically perfect through biological therapy. In cholera and the ingestion infections in general we have such reliable methods of prevention that the extension of an epidemic among troops carries reproach upon the medical officers in charge. Are we powerless only in the control of epidemic respiratory infections? Must we await exact perfection of method in biological immunization, through vaccines and sera, to be applied only after a biological diagnosis of each individual case?

It seems to me that we are justified in carrying out in future crises experiments upon a scale so large as to give valuable data, favorable or otherwise, with mixed vaccines of all strains of pneumonia-producing organisms, including the influenza bacillus. The employment of millions of doses of triple typhoid vaccine and three-strain pneumococcus vaccine in the U. S. Army, a tetravaccine of cholera, paratyphoids, and typhoid in Serbia (100,000 doses and more) have shown the harmlessness of such combinations, and there seems to be enough promise of good results to warrant such experiment with the pneumonia and influenza group.

For the time limits of epidemic prevalence at Camp Meade we will take the dates of September 20 (with 68 influenza admissions) and October 20 (with 12 admissions). The total admissions for the period covered by these dates numbered 11,403 in a population of 42,300. The deaths numbered 763. The pneumonia cases numbered 2,877. The peak day was September 30, for which day 1,590 influenza cases were reported.

The average strength of command for the period was 42,300, and we find that one man from every 3.7 men incurred influenza (269 per 1000, or 26.9 per cent.) and that one man of every 55.5 men in the cantonment died (18 per 1000, or 1.8 per cent.) within 30 days. As every pneumonia case was primarily an influenza case, we find that pneumonia complicated one of every 3.97 cases of influenza, or 25.7 per cent. One man out of every 15 cases of influenza died (a case mortality of 6.7 per cent.) and one man out of every 3.77 cases of pneumonia died (a case mortality of 26.5 per cent.).

I have small patience with the statement so current of late (made incidently by some very eminent men) that we know nothing about influenza. For my part, I must dispute the truth of such statements, and those of you who remember the great influenza epidemic of a quarter of a century ago and have been familiar with the disease ever since that time will agree with me, I feel sure.

We know a great deal about it. Medical literature of twenty years ago contained perfectly adequate descriptions of the disease as it appeared in 1918. Moreover, failure to know influenza is due to a failure to become acquainted with the disease as it occurs sporadically and endemically in every community, every year. The added features of high infectivity and intense virulence, the causes of which features we certainly do *not* understand well, were the distinguishing characteristics of the recent epidemic. To say that we know nothing of influenza and its complications because its bacteriology is in dispute, is as unreasonable as it would be to contend that we know nothing of typhus or yellow fever, or perhaps of scarlet fever, which are all of debatable causation. We know the gateways of infection. We know the vehicles of infection. Moreover, we know that the administration of composite vaccines representing all of the bacteria known or believed to cause influenza and the various pneumonias is harmless, hopeful, and apparently logical. We know that the administration of immune sera or convalescents' plasma or compound antigens for exciting protective reactions are also logical.

I cannot but feel regret at the attitude shown by so many clinicians, both in the army and outside of it, when they refuse to make use of these agencies, as for example, refusing to use polyvalent pneumococcus serum in an untyped pneumococcus pneumonia or an antipneumococcus or antistreptococcus serum in influenza, because, forsooth, dispute exists concerning the primal cause of influenza, a disease which is so constantly a mixed infection early in its course.

In conclusion it seems fair to ask the profession to assume an attitude of willingness to accord a therapeutic test to efforts at prevention apparently as well grounded as are these measures based on biological study. For years we followed empiricism

and later drug therapy based on physiological drug action as determined in health. Surely the profession, in the light of its recent demonstrated helplessness, is not falling backward when it lends support to and engages with open mindedness in clinical investigations such as these.

Fifth Street and City Line.

THE THERAPEUTICS OF ASPIDOSPERMA.*

By REYNOLD WEBB WILCOX, M.D., D.C.L.
NEW YORK.
PRESIDENT OF THE AMERICAN COLLEGE OF PHYSICIANS.

The remedy known as Aspidosperma—synonym, Quebracho—is the dried bark of *Aspidosperma quebracho blanco* Schlechtendel, from Argentina. It became official in the ninth edition of the United States Pharmacopeia, on September 1, 1916.

Composition.—It contains at least six alkaloids: Aspidospermine, $C_{22}H_{30}N_2O_2$, dose 0.016 to 0.03 gm. (¼ to ½ gr.); Aspidospermatine, $C_{22}H_{28}N_2O_2$, which is isomeric with Aspidosamine, Quebrachine, $C_{21}H_{26}N_2O_3$ dose 0.06 to 0.12 gm. (1 to 2 gr.) which is isomeric with Hypoquebrachine and Quebrachamine, none of which are official. The dose of pure crystallized aspidospermine is from 0.0016 to 0.003 gm. (1/40 to 1/20 gr.). The aspidospermine of commerce (amorphous aspidospermine, dose 0.016 to 0.03 gm. (¼ to ½ gr.) is not a pure principle but probably contains all the alkaloids in the bark; but it may consist chiefly of aspidosamine.

The preparation commonly employed is the fluid extract made by percolation with glycerin, alcohol, and water, of which the dose is 4 mils (one fluid drachm). This is not miscible with water and has a decidedly unpleasant taste.

Action.—It would seem that the various alkaloids have different effects upon the organism, and in some respects are more or less antagonistic to each other.

The fluid extract, taken internally, has an astringent and slightly aromatic taste. In small doses it acts as a bitter, so far as the stomach and intestines are concerned, increasing the secretions of the digestive tract.

Circulation: There is a temporary fall of blood-pressure which may persist if the dose is large. This lowered blood-pressure is not due to paralysis of the vasomotor system, but, since the pulse is not slowed, it probably results from a depressant effect upon the cardiac motor ganglia or upon the muscle. After large doses this fall in blood-pressure is marked.

Blood: The blood in the veins as well as in the arteries is bright red in color, due probably to increased respiration, although it has been suggested that it, by direct action, enables the blood to take up an unusual amount of oxygen; if asphyxia supervenes, it becomes darker in all parts of the body. There is apparently no diminution in the oxygenating power of the blood and no spectroscopic changes.

Respiration: Aspidosperma causes, in small doses, an increase in depth, and in larger doses a marked increase in both rate and depth, of respiration, the latter being especially pronounced; the volume of air moved may be quadrupled. This condition of dyspnea is not due to any effect on the blood because it may be eliminated by section of the vagi. There is some action upon the respiratory center because, after the administration of large doses to animals, the respirations become arrhythmic, slower, and shallower, and finally cease, which results are observed even after section of the vagi.

The expectorant effects are not entirely due to the nauseating action of the Galenical preparation, but rather to depression of the excitability of the respiratory center similar to that produced by apomorphine and by hydrocyanic acid, so that the disposition to cough is lessened. However, the remedy possesses no narcotic action. Since it increases bronchial secretion and is a motor depressant it should be classed among the depressant expectorants. Intravenously in animals it is stated that it may produce intense congestion and ecchymosis in the lungs.

Nervous System: The central nervous system is but slightly affected by ordinary doses. The prolonged use of this drug not uncommonly causes somnolence, vertigo, headache, ptyalism, and nausea. In animals, however, large amounts, through their action upon the brain and spinal cord, cause tremors, increased reflexes, and, if the dose is large enough, absence of all reflexes, general muscular weakness, and finally paralysis.

Temperature: It is said to reduce body temperature, but the method by which this result is produced is conjectural.

The action of the various alkaloids has not been ascertained with accuracy. The following statements are to be found in the literature:

Crystallized aspidospermine increases respiratory movements, slows pulse rate, and lowers temperature. Large doses produce irregularity of rhythm and failure of respiration. It acts similarly to apomorphine in large doses.

Amorphous aspidospermine produces temporary fall of blood-pressure which is permanent if the dose is large. During the period of low pressure irritation of the central end of the vagus produces a rise of temperature.

Aspidospermatine, which is isomeric with aspidosamine, acts more especially in reducing blood-pressure.

Quebrachine, which is isomeric with hypoquebrachine and quebrachamine, acts chiefly upon the respiratory center. Since it passes rapidly through the alimentary canal it is slowly absorbed. Its elimination takes place chiefly through the kidneys, increasing their secretion. This elimination begins within a few hours and is complete within 24 to 48 hours. It has a similar action to that of apomorphine; vomiting is not a prominent symptom, but, should it be produced, it is of central origin.

Therapeutics.—It is a valuable remedy when the respiration is embarrassed, as in emphysema, chronic bronchitis, or chronic pneumonia; in many instances the relief is almost immediate. Given in proper doses it relieves not only the dyspnea but also the cyanosis and sense of suffocation. It appears to assist the oxygenation of the blood as well as to stimulate the respiratory center. Aspidospermine represents fairly well the activity of the drug with the further advantage that it may be used hypodermatically in dose of one-half grain (0.03 gm.).

*Read at Atlantic City, N. J., on June 7th, 1919, at the Twentieth Annual Meeting of the American Therapeutic Society.

It may relieve symptomatic asthma when due to uremic conditions, and possibly when arising from cardiac failure. When dyspnea is due to cardiac hypertrophy relief is more certain not only because of the depressant effect of the remedy upon the cardiac musculature, but as well because of its action upon that part of the nervous system which governs respiratory movements, and its influence may even extend to the cardiac innervation. The asthmatic symptoms of secondary anemia are often markedly relieved because it is believed that the remedy increases the power of the hemoglobin to take up oxygen, although it is not explained in what way this may be accomplished. It is probable, however, that when asthma is not symptomatic of serious organic lesion, the effects of the remedy will be constant and satisfactory. Usually its use is not so satisfactory during the paroxysms as are other remedies. It is not indeed curative, but it possesses a marked action in preventing a recurrence of the attacks. After its administration there is usually a feeling of warmth in the head, some perspiration, and frequently slight salivation. The dose required for this purpose is from ½ to 1 teaspoonful (2 to 4 mils) every two to four hours, but if long continued it is likely to cause nausea. Prolonged administration produces no alterations in other functions or organs excepting such as have been noted above.

While we must concede that the effect of the remedy upon respiration is unique, we are not prepared to advocate the use of it for the dyspnea of mitral insufficiency (and I am quoting an eminent clinician), unless that lesion were well compensated by cardiac hypertrophy. Nor indeed can we go so far as to call it the "digitalis of the lungs" in that it relieves dyspnea whether from purely nervous disorders or when due to anatomical alterations in the respiratory or circulatory apparatus.

There is no doubt but that aspidosperma is a valuable remedy for the relief of some instances of disease in which dyspnea is a persistent and important symptom, but its employment is largely empirical, in spite of the valuable and important work of our own Wood. In order that its logical uses and its limitations may be determined, the pharmacology of its various alkaloids must be worked out in the chemical and physiological laboratories, and it must be employed in actual practice upon patients in order that it may be used with confidence and we may be certain of obtaining uniformly satisfactory results.

Forty years of clinical observations have established the value of the remedy so that it has been properly admitted to the pharmacopeia. Personally I have often obtained brilliant results from its administration and occasionally equally inexplicable failures.

679 Madison Avenue.

Typhoid Fever in Bolivia.—According to Villazon, typhoid is very frequent in Bolivia, especially among the Indians. As a contributing cause the author enumerates neglect of personal hygiene. The Indian does not bathe nor wash his mouth, never cleans his dwelling, and drinks pure alcohol in large quantities. When stricken he cannot be made to diet. The result is a mortality of 90 per cent. Preventive vaccination gives excellent results, while curative vaccine appears to do more for the patient than any other method.—*Gazette des hôpitaux.*

Medicolegal Notes.

Construction of Harrison Narcotic Act.—The Circuit Court of Appeals, Fourth Circuit, holds that the mere issuance of a prescription by a physician, to be filled by any druggist, without participation by the physician in the sale under it, would not be a sale or such dispensing or distribution as amounts to a sale under section 2 of the Harrison Narcotic Act. What the statute forbids is sale, barter, exchange, or gift, including such distribution and dispensing by a physician not in the course of his practice as would amount to participation in a sale, barter, exchange, or gift.—Foreman v. United States, 255 Fed. 621.

In another proceeding for violation of the statute, the Supreme Court, in answer to three questions propounded to it by the Circuit Court of Appeals, made the following rulings: The first sentence of section 2 of the act prohibits retail sales of morphine by druggists to persons who have no physician's prescription, who have no order blank therefor, and who cannot obtain one because they are not of the class to which such blanks are allowed to be issued. The sentence, so construed, is held not unconstitutional. A physician's order for morphine issued to an habitual user, not in the course of professional treatment for a cure, but to keep him comfortable by maintaining his customary use, is not a "physician's prescription" within the meaning of the section.—Webb v. United States, 39 U. S. Sup. Ct. 217.

In both cases the Chief Justice dissented because he was of opinion that the court below correctly held the act of Congress, in so far as it embraced the matters complained of, to be beyond the constitutional power of Congress to enact because to such extent the statute was a mere attempt by Congress to exert a power not delegated, that is, the reserved police power of the states. Mr. Justice McKenna, Mr. Justice Van Devanter and Mr. Justice McReynolds concurred in this dissent.

Form of Hypothetical Question.—In an action for personal injury to the plaintiff's arm the plaintiff's counsel, after detailing a suppositive occurrence based upon the facts disclosed in evidence as to the way in which the plaintiff was injured, asked her physician if the condition he found in the plaintiff's arm "might, could, or would, in your opinion, result from the circumstances I have described to you." The inclusion of the word "would" in the question, objected to by the defendant, was held not error, the words "might, could, or would "being the proper ones to use in connection with a hypothetical question of this kind.—Eidson v. Metropolitan Street Railway Co. (Mo.), 209 S. W. 575.

The Circuit Court of Appeals for the Second Circuit holds that what facts a hypothetical question must cover are to be determined by the sound discretion of the trial judge. But a hypothetical question should ordinarily be based, at least upon the direct examination, upon facts of which there is such evidence that a jury may reasonably find that they are established; though it is not in general essential that each hypothetical question should embrace every fact which it might be contended should affect the expert's judgment. —Napier v. Greenzweig, 256 Fed. 196.

Workmen's Compensation—Medical Services.—Under section 6 of the Nebraska Workmen's Compensation Act, the Nebraska Supreme Court holds that an employer who offers to furnish without charge to an injured employee the reasonable services of a competent physician and medicines as and when needed, and within the value and for the time contemplated by the act, cannot be held liable for such services by the employee who has refused such offer by the employer and has obtained such services and medicines elsewhere. —Radil v. Morris & Co. (Neb.), 170 N. W. 363.

Claims for Medical Services.—On an appeal from a judgment for the plaintiff in an action to recover for medical services, where there is no evidence in the record of any cross-examination as to one of the items of service which is set up in the statement of facts nor of anything in rebuttal of the claim therefor, the Illinois Appellate Court will not say that the allowance of the claim for such item was error.—Moldenhauer v. Moskalczak, 211 Ill. App. 462.

MEDICAL RECORD.

New York, October 25, 1919.

TROPICAL IDIOPATHIC ABSCESS OF THE SPLEEN.

TROPICAL idiopathic splenic abscess is observed in malarial countries and arises in suppurating splenitis. These abscesses resemble those of the liver met with in tropical countries, but they are uncommon. Unquestionably, malaria plays the principal etiological part in the process, as is evident from the case reports. The affection develops either during the acute phase or in malarial cachexia. Trauma, excessive fatigue, and chilling of the body, are adjuvant factors. The exact part played by malaria is not clearly understood, but it probably predisposed the subject on account of the profound changes occurring in the splenic parenchyma; as Laveran's organism does not belong to pyogenic agents, its presence in the spleen cannot give rise to abscess. In the few cases in which examination of the pus has been possible it has been found sterile, and the same is true in the case of the liver. The similarity between abscess of these two organs is made more striking from the fact that intestinal disturbances occur in both. Severe diarrhea has been met with in several instances of splenic abscess.

The abscess develops in the midst of the splenic parenchyma and provokes a high-grade hyperemia in the surrounding tissues. The pus is sometimes greenish white, or again it contains blood and is brownish. Microscopical examination in one case showed some red blood corpuscles, a large number of leucocytes, for the most part small polynuclears and a few mononuclears of all dimensions. In comparison with other leucocytes, the neutrophiles were represented in enormous proportion.

There may be complete absence of pain, or it may be very severe, extending to the shoulder and scapular region. The pain often results from a concomitant perisplenitis. If the abscess is present on the splenic surface it may assume the form of a painful tumefaction with an elevation of the local surface temperature; shortly after this, fluctuation can be detected. If the abscess is deeply seated, or if it develops on the internal surface of the organ, it may be inaccessible to external palpation.

The duration of the evolution of the process varies from some weeks to several months. The patient's physical state is always greatly compromised; there is usually a marked degree of emaciation, physical weakness, dyspnea, severe sweating, and diarrhea. The fever is at times continued, or it may be intermittent. In some few cases the process has been apyretic.

If surgical measures are not resorted to, death is the outcome in most cases, because the pus will rupture into some one of the hollow viscera or peritoneum, and it is only very infrequently that it has made its way to the surface through the abdominal parietes. According to the statistics collected by Grand Mourset, in cases of splenic abscess of various origins the pus ruptured into the lung in four cases, transverse colon three cases, pleura two cases, stomach three cases, splenic vein three cases, vagina and thoracic wall each one case.

The diagnosis is often difficult. It is impossible to say with certitude whether the case is one of purulent periplenitis, circumscribed abscess in the splenic region, or an abscess of the spleen, because the symptomatology is the same in all. The differential diagnosis between splenic abscess and a perinephritic phlegmon may offer great difficulties. If the pus collection develops in the upper pole of the spleen, and if it forces up the diaphragm it may easily be mistaken for a pleural empyema. When the spleen is adherent to the anterior abdominal wall a simple incision is all that will be required. In exceptional cases, however, and when it is technically possible, splenectomy should be done.

VENEREAL PROPHYLAXIS.

WHILE all are agreed that the venereal diseases constitute an ever-present menace and that every possible means should be resorted to in order to check their spread, there exists a wide diversity of views as to the form such means should take. There are those who assert that venereal diseases are comparatively easy to prevent and even go so far as to say that they can be extirpated. Most of these optimists pin their faith to direct prophylaxis or to early preventive treatment. That is to say, the employment of the Metchnikoff method either before intercourse or so soon thereafter as to prevent infection from gaining a foothold. It has been stated on several occasions that such measures have been used with highly successful results among troops, notably among the Australian forces serving in Egypt and in the near East. So insistent have been in Great Britain the advocates of the Metchnikoff methods that the British Ministry of Health has taken up the question and has appointed an Inter-Departmental Committee to consider what concerted measures should be taken by the departments concerned to mitigate the dangers of the dissemination of tropical and other diseases among the civil population arising from the demobilized troops. This committee recently published a memorandum dealing with the venereal diseases. The committee considered that this was the matter of paramount importance, and, more-

over, thought it well to consider first the advisability or otherwise of the Government encouraging officially the sale of "packets" as a preventive measure. It is stated in the memorandum that in order to acquire a full and adequate presentation upon the question of prophylaxis, the committee invited special medical representatives to give evidence, including officers of the Canadian, Australian, New Zealand, and the United States Army Medical Corps, as well as of the British Expeditionary Force and others. The committee, after weighing the evidence, finally came to the conclusion that the official recommendation of a packet system to the civil community was neither desirable nor practical.

This decision has given rise to a good deal of hostile feeling on the part of the supporters of the method of prophylaxis investigated, some of whom have not hesitated to express their opinions with the fullest freedom. In fact, the writer of a leading article in the London *Times* attacks the conclusions of the report and its authors in unmeasured terms. The editorial in question insinuates that the conclusions are based not on the practical and scientific evidence given but on the moral aspects of the case. It is further insinuated that a clamorous minority swayed the decision in this direction. The committee, however, does not stigmatize the "packet" system as useless or dangerous. It merely holds that from the evidence supplied it would not be justifiable to place the official seal on the system as desirable or practical for adoption by civilians.

On the other hand, the memorandum of the committee seems to lay most stress on the moral bearings of the situation, and the question appears to be, did the committee sift and weigh the statistical, scientific, and medical evidence as thoroughly as its importance demanded? Were the findings of those responsible for the use of the system among the Australian and New Zealand troops in Egypt justified; was the method successful among some of the Italian troops; and has it been used with beneficial effects among a civil population? None of these points have been made clear, and the matter seems to be in as confused a state as ever. The verdict of the committee is "not proven" and is unsatisfactory on account of being so indefinite. It both praises the method and damns it. It is true that the fact that the system has been successful in armies constitutes an absolute reason why it should produce similar results among civilians, but it does not constitute a valid reason why the matter should not be closely investigated from the scientific and practical points of view, and if after this investigation it is shown that it will prevent the spread of venereal diseases in armies then efforts should be made to overcome the obstacles to its use in civil life.

First of all, it must be definitely shown what the effects of its use have been among troops, and this phase of the matter does not appear to have been sufficiently elucidated by the committee, or if elucidated has not been sufficiently explained in the memorandum. Of course, moral considerations must be taken into account, but when a prophylactic system is established upon a proven basis of efficiency no argument can prevail against the necessity of its employment. The venereal problem is the most pressing problem of the day; it is a world-wide problem, the solution of which would usher in an era of health at present only dreamed of. It would be the greatest triumph of preventive medicine, for in proportion as venereal disease is the parent of many diseases, so its prevention would signify the prevention of untold sickness and suffering.

"Noma" of the Hand.

Noma has been so associated with the mouth that to use the term for gangrene in any other locality produces a sense of discord even though the condition is in rare cases associated with the vulva in childhood. It also puzzles the average reader when he finds gangrene in certain localities called noma, when precisely the same type of gangrene can conceivably occur almost anywhere. Did any one ever call a spontaneous gangrene in the noma area by any other term? There is of course an individuality about the disease when it complicates the acute exanthemata of childhood, but a study of noma in general shows that it attacks adults and need not complicate infectious fevers. In the *Finska Läkaresällskapets Handlingar* for July-August Elving describes and illustrates a case of noma of the hand. The patient was a boy aged 5 years. The general condition was one of physiological misery. The gangrenous process in the right thumb was not a complication of any acute general infection. A brother two years younger had suffered from an ulcerated stomatitis which seemingly had caused a certain amount of gangrene and had been diagnosticated as noma, but the patient had remained free in this respect. It was necessary to perform an amputation in the forearm, as the process had extended from the thumb to the hand. The author appears to connect the gangrene with a history of scarlatina and pneumonia two years before and states that spontaneous gangrene of the extremities occasionally complicates or follows acute general infections—hence the author's use of the term noma. Of great interest is the fact that the organisms peculiar to Vincent's angina were present in the tissues, or rather the spirilla were surely found while the fusiform bacilli were more open to doubt, although bacilli coexisted. This find would explain the stomatitis and gangrene of the brother and also suggest contagion to the older child.

Inversion of the Oculocardiac Reflex.

According to Laval and Girou in the *Gazette des hôpitaux* for July 19 study of the oculocardiac reflex during the war has led to considerable advance in our diagnostic repertoire. This is true especially of severe injuries to the cranium and nerve centres in which the sympathetic or vagus is rendered hyperexcitable. In shock the reflex is practically abolished. Diminution of the reflex is also seen in wounds of the skull and encephalon and brady-

cardia when present is not in any sense due to the reflex but to increased intracranial tension. In a case of suppurative otitis media with a pulse of 48 to the minute the results of study of the reflex were as follows: The subject, who had seemed to be on the road to recovery, was suddenly attacked by cerebral symptoms which became aggravated and led to intervention. An abscess was found in the cerebellar fossa and the course of the post operative period showed fluctuations necessitating renewed intervention. The pulse started to rise, again fell, and then increased gradually to normal. Before the intervention, with pulse at 48, the oculocardiac reflex was inverted to minus 108. After relief of the intracranial tension the pulse rose to 70 but the reflex was still inverted. A few minutes later the reflex was zero but after the evacuation of the pus it became plus 56. From then onward it fluctuated between 45 and 60 until it became stabilised at 48 plus. The significance of an inverted reflex is not specific for such cases, for it is seen in various conditions and is even common in good health; but in connection with intracranial troubles, especially otogenic, it furnishes valuable information concerning the action of the intraocular pressure on the vagus and sympathetic nerves.

Pyretotherapy.

In addition to the cures and arrests of disease by intercurrent fevers, the number of drugs now known to cause fever and to produce therapeutic results in part because of that property is constantly increasing. In 1896 Hallopeau and Roger cured tuberculous lupus through the fever induced by the toxins of the streptococcus and prodigiosus. According to Konteschweller in *La Presse Médicale* for August 14 this was the first scientific use of pyretotherapy, and he strangely gives not the slightest credit to Coley in this connection for his long known method of curing sarcoma by practically the same resource. At the present time as distinguished from earlier years we are using substances intravenously and this fact is at the bottom of the great increase in pyretogenic substances. Even intramuscular injections, as those of grey oil, often cause temperature rise. The new colloidal substances when thrown into the veins cause severe chills followed by high fever, and in some affections the benefit derived can be explained only through this phenomenon. The most extensive group of substances of this sort, however, comprises the various biological products of which tuberculin was long the sole member, and which along with sodium nucleinate long remained our only resources for producing artificial fever as a general method of treatment, both substances having been tested in paresis. The use of these substances has culminated in the injection of foreign protein for a great variety of conditions in which, according to the author, much of the benefit is traceable to the febrile movement set up.

Influenza in the Insane.

In September, 1918, when the influenza pandemic appeared in the second wave in Switzerland the infection entered the Insane Asylum at Bel Air, having been conveyed therein by the contractors for provisions and the gardeners. According to a report by Demole and Alikhan in the *Revue médicale de la Suisse romande* for August, the total asylum population was 507 and of this number 189 developed the disease. The victims were chiefly young subjects. Three insane and a keeper met death. Evidently quite distinct from the normal insane population were 25 subjects who had been rendered insane by the disease and were interned during the 6 months following the pandemic. In contrast with this material, the 189 insane who contracted the disease did not show any psychic reaction, while as already shown the mortality was very low. These figures would suggest that the insane as a class resist the complications of the disease. During the month of June the Asylum was practically immune from the first outbreak of the pandemic, for although some of the attendants were infected outside the institution the contagion did not spread among the inmates. To a certain extent the spread during the second wave could be traced from man to man, and the incubation was 48 hours approximately. All prophylaxis was unavailing, including the use of the mask, isolation alone at the earliest moment seeming to be of some benefit.

News of the Week.

The Church Considers Revival of Ministry of Healing.—The Rev. Dr. William T. Manning, rector of Trinity Parish, New York, offered a resolution in the House of Deputies of the Episcopal Church at the recent general convention in Detroit, providing for the appointment of a committee of three bishops, three presbyters, and three laymen "to consider the fuller recognition of the ministry of healing in the Church and the need of its revival under proper sanctions and safeguards." The resolution was unanimously adopted and sent to the House of Bishops for concurrence.

Red Cross Will Keep Base Hospitals.—The fifty Red Cross base hospitals in America, eight of which are in New York City, together with their medical, surgical, and nursing staffs, which were established during the war, are to be held intact for peace time emergencies, such as great disasters or epidemics. The Army is cooperating with the Red Cross by providing each base hospital with a unit of equipment in accordance with military standards, stored in a Government storehouse as near as possible to the city where the base hospital is located.

New Appointments at Cornell University Medical College.—Cornell University Medical College announces the following new appointments to the Medical Faculty: Dr. E. F. DuBois, assistant professor of medicine, director of medicine, Bellevue Hospital; Dr. Oscar M. Schloss, professor of clinical medicine, Department of Pediatrics; Dr. Henry H. M. Lyle, assistant professor of surgery; Dr. Jeremiah S. Ferguson, assistant professor of clinical medicine, Department of Pediatrics; Dr. Nellis B. Foster, assistant professor of medicine and associate attending physician to New York Hospital; Dr. John C. A. Gerster, assistant professor of clinical surgery; Dr. Charles V. Morrill, assistant professor of anatomy; Dr. Robert Chambers, assistant professor of anatomy. The College

opened its twenty-second annual session on September 29, 1919, with a registration of 218 students. There are in addition 40 medical students in the first year in medicine at Cornell University, Ithaca, N. Y. The Annual Address to the students was delivered by Dr. Graham Lusk, professor of physiology.

Dr. P. Hermann Geist, who organized the American Relief for Children in Vienna and is still at the head of that work, has been asked to become food dictator for the whole city, and will accept the position if Mr. Hoover approves.

Dr. F. Florencio Suarez, vice-consul of Spain in Ponce, Porto Rico, is in New York making a study of the sanitary conditions of the city.

Dr. Samuel Lloyd, who served as a Colonel in the Medical Corps of the United States Army, has returned from France and resumed his practice at 50 East Forty-second Street, New York City.

Tuberculosis in the Balkans.—A report from the American Red Cross headquarters in Bucharest asserts that the tuberculosis death rate in Rumania, Serbia, Albania, and Montenegro is the highest in the world. A Red Cross worker in Albania states that she finds tuberculosis in almost every family and that about 80 per cent. of the people are affected. In Montenegro the death rate from tuberculosis among children is said to be fearfully high. This is attributed partly to infected milk, as tuberculosis is very prevalent among the cattle of that country. There is said to be distressing need for tuberculosis sanatoriums. The Red Cross feels that it is beyond its province to provide such institutions on the scale that would be needed.

Germ of "Deer-Fly Fever" Discovered.—According to an announcement by the United States Public Health Service a germ known as *Bacterium tularense* which had been isolated by Drs. McCoy and Chapin of the Public Health Service as the causative agent in a plague-like disease among rodents, has been found to be the cause of a disease occurring among the rural population of Utah called "deer-fly fever." Thus far about two dozen cases of this disease have occurred in Millard County, Utah, in each of the years 1917, 1918, and 1919. The fever is said to be somewhat similar to ordinary septicemia and lasts from three to six weeks. The first case known to have ended fatally was reported in 1919. Whether the disease exists elsewhere is not known but the Public Health Service wishes to direct the attention of physicians to cases of this kind. According to popular belief the disease is initiated by a fly bite on some exposed portion of the body.

Exposition of Municipal Equipment.—A permanent exposition of municipal equipment is being established at the Grand Central Palace, New York. Among the features of this exposition are a demonstration of pasteurization of milk, and the testing of clinical thermometers, a model hospital section, and a health center.

Medical Society Elections.—The Holyoke Medical War Veteran's Association, recently organized in Springfield, Mass., has elected the following officers for the ensuing year: *President,* Dr. William P. Ryan; *Vice-President,* Dr. George L. Gabler; *Adjutant,* Dr. Robert E. Cleary.

The Milwaukee Physicians' Association, at its annual meeting held October 2, 1919, elected the following officers for the ensuing year: *President,* Dr. A. R. T. Grob, *Vice-President,* Dr. E. M. Rice; *Secretary and Treasurer,* Dr. Hugo P. Siekert; *Directors,* Dr. E. B. Taylor, two years, and Dr. F. M. Smith, three years.

The National Society for the Promotion of Occupational Therapy, at its third annual meeting held in Chicago, September 8-11, 1919, elected the following officers: *President,* Mrs. Eleanor Clarke Slagle, Chicago; *Vice-President,* Dr. Herbert J. Hall, Marblehead, Mass.; *Secretary,* Mr. Louis J. Haas, White Plains, N. Y.; *Treasurer,* Miss Marion R. Taber, New York.

The New Mexico State Medical Society, at its annual meeting in Albuquerque, N. M., October 5, 1919, elected the following officers for the ensuing year: *President,* Dr. H. V. Fall, Roswell; *First Vice-President,* Dr. C. A. Russell, Artesia; *Second Vice-President,* Dr. F. E. Mera, Sante Fe; *Third Vice-President,* Dr. F. L. Crail, Las Vegas; *Secretary,* Dr. F. E. Tull, Albuquerque; *Treasurer,* Dr. J. W. Elder, Albuquerque.

The Minnesota State Medical Association, at its annual meeting held in Minneapolis, October 3, 1919, elected the following officers for the ensuing year: *President,* Dr. J. H. Adair, Owatonna; *First Vice-President,* Dr. E. M. Clay, Renville; *Second Vice-President,* Dr. C. B. Lewis, St. Cloud; *Secretary-Treasurer,* Dr. F. L. Beckley, St. Paul.

The Lexington (S. C.) County Medical Association, at its annual meeting in Lexington, elected the following officers for the ensuing year: *President,* Dr. H. J. Mathias; *Vice-President,* Dr. D. R. Kneece; *Secretary,* Dr. I. J. Wingard.

The Holyoke (Mass.) Medical Association, at its first meeting since the war, held October 8, 1919, elected the following officers: *President,* Dr. I. H. Farr; *Vice-President,* Dr. Robert E. Cleary; *Secretary-Treasurer,* Dr. F. A. Mead.

Memorial Tablet Unveiled.—The Sisters of St. Francis of St. Anthony's Hospital, Oklahoma City, have presented a bronze tablet to the hospital in memory of Maj. Robert Lord Hull and Captain Frank Bruner Sorgatz, members of the hospital staff who lost their lives while in military service during the epidemic of influenza last winter. Unveiling ceremonies were held on September 19.

Doctors Continue to Raise Fees.—The Spokane (Wash.) Medical Association voted on October 9 to raise its fee schedule 40 per cent. above those of 1914. Under the new schedule a special charge of $1 to $2 is made for every additional mile outside the city limits. Consultation or advice by telephone ranges from $1 to $4. An additional charge is also made for contagious disease calls. The physicians of Roxbury, Mass., of Fall River, Mass., and of Milford, N. H., have also adopted a schedule of minimum fees. Under these schedules office calls are $2 and house calls $3, and there is a corresponding increase in the charge for obstetrical and surgical cases.

Salem Doctors Increase Fees.—Following a meeting on September 25, Salem doctors announced that they had found it necessary to increase their fees and that the new schedule would go into effect on October 1. The new fee schedule makes office calls

$1.50 and house calls $2. Calls between 6 P. M. and 7 A. M. range from $2.50 to $3. Obstetric cases have gone up from $15 to $20.

Obituary Notes.—Dr. DANIEL P. COOK, a graduate of the University of Michigan, Department of Medicine and Surgery, in 1881, died at his home in Clay Center, Kas., on October 2.

Dr. WILLIAM SUNDERLAND MOTT, a graduate of the American Medical Compend, Toledo, Ohio, in 1885, died suddenly at his home in Salem, Ore., on October 3, aged 64 years.

Dr. JAMES PERRY DUCKETT of Anderson, S. C., died in a local hospital, on October 10, aged 68 years. He was a graduate of Jefferson Medical College, Philadelphia, in 1874, and was a member of board of health and city council of Anderson for some years.

Obituary.

STEPHEN HENRY LUTZ, M.D.,

BROOKLYN, NEW YORK.

Dr. STEPHEN HENRY LUTZ of Brooklyn, president of the Kings County Medical Society, died from heart disease at his home on October 17, aged 48 years. Dr. Lutz was a graduate of the College of Physicians and Surgeons, New York, in 1894, a Fellow of the American College of Surgeons, a member of the American Otological Society, the American Laryngological, Rhinological and Otological Society, of the New York Otological Society, of the Medical Societies of the County of Kings and of the State of New York, and of the American Medical Association. He was surgeon to the ear department of the Brooklyn Eye and Ear Hospital, aural surgeon to the Brooklyn Eastern Dispensary and Hospital, consulting laryngologist to the Bedford Dispensary, otologist to the Bushwick Hospital, and consulting aurist to the Jamaica Hospital.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent)

LONDON, Sept. 26, 1919.

Industrial Fatigue.—Industrial medicine is, in the very nature of things, greatly to the front at the present time. Dr. H. M. Vernon is one of the principal British authorities on the subject and has contributed recently a report to the British Industrial Fatigue Research Board. The report in question deals with the tinplate industry and states without reserve that output in the industry depends directly upon good ventilation. Furthermore as is well known our views regarding what is good ventilation have undergone considerable revision. It is movement of the air chiefly which signifies satisfactory ventilation. Lack of stimulation by these air currents brings about lethargy and weariness and hinders work, and therefore the employer who keeps a "stuffy" factory robs himself. Vernon found that output in the tinplate industry is affected even by the weather. If 100 be taken as the average output, it appears that at an external temperature of 38° Fahr. the output was 104, and at an external temperature of 62° Fahr. a well ventilated factory had an output of 98. The output curve in short follows the temperature curve. Thus the output is highest in the winter months and lowest in August. But the "weather" inside a factory may be arranged by means of ventilation. At an external temperature of 67° Fahr. a well ventilated factory had an output of 98. At the same external temperature a factory with no ventilation had an output of 90 only. In the latter case lack of ventilation was obviously a source of marked economic loss to the employer. However, a more interesting point was one raised by Lord Leverhulme who suggested that instead of the usual eight-hour shift system in which, as a rule, the machinery ran only forty-four hours a week, the work should be done in two six hour shifts every day, viz., from 7 A. M. to 1.30 P. M., and from 1.30 to 10 P. M. with half-hour breaks for meals.

This scheme was made the chief matter for debate at a joint meeting of the Economic Science Section with the Physiology Section and the Psychology Sub-Section at the recent congress of the British Association for the Advancement of Science. Dr. H. M. Vernon opened the discussion. He pointed out that the cost of running the machinery in two six-hour shifts every day was considerably less than the usual eight hour shift system. Available evidence did not indicate that there would be much improvement of output in many industries. He did, however, draw attention to the fact that in the cotton-spinning mills of the United States a reduction of two or three hours in the weekly hours of work caused an almost proportional decrease of output. As has been stated several times, very different results were observed in certain munition industries. Men, for instance, engaged in the somewhat heavy operation of sizing fuse bodies increased their hourly output 39 per cent. when their nominal hours were reduced from 67 to 56 per week, and their actual hours of work from 58.2 per week to 50.6 per week, and their total weekly output went up 21 per cent. The same results were observed in the case of women engaged in heavy labor. The reason why reduction of hours caused such different effects in different industries was because of the various degrees to which the work was controlled by the personal element, and by machinery. Vernon thought it was likely that in most industries the eight-hour day did not cause more than a moderate amount of physical fatigue. Monotony of work had a worse effect than long hours. Mr. P. Sargent Florence reported on investigations made by a committee under the National Research Council of America in cooperation with the U. S. Public Health Service. Their main report which would appear shortly, made a comparison between a ten-hour engineering factory and another of eight hours in the matter of output, accidents, lost time, and labor wastage. They had brought out the importance of the different types of work in producing fatigue, and the significance of rhythmical movements in industry. The general effect was in favor of the eight-hour plan. The average age of the worker in the eight-hour factory was 31, and in the ten-hour factory 29 to 30. This suggested the problem of what happened to those over 45. It seemed as if the strain of industry was one that told very heavily and that workers could not last long under it. Conditions of

labor ought to be made such that persons could continue longer at work. The effect on physical conditions was due to noise, harmful air and light conditions, muscular and eye strain. The presence of noise was the most important. The time interval between operations or between various steps in operations could be measured and such measurements could be used as an index of the rhythm. A method was devised of fitting up the machine to be studied with electrical contacts so that each step in the operation could be recorded automatically. The fatigue of the day did not seem to lessen the rhythm of the operation. Distraction, such as counting the ringing of a bell, did not seem to interfere with the rhythm. He suggested that rhythm might aid in avoiding fatigue. It relieved attention and its consequent fatigue.

Miss C. Smith Rossie spoke on physiological fatigue and village meeting halls. Educational fatigue she said was always coincident with nerve exhaustion. That was one reason why adult continuation schools had not much success. To make them successful the surroundings where they were held must be as tonic as possible. Miss Rossie cited Denmark as an example of making rural meetings successful. Almost every Danish village to-day had its own meeting-hall, adapted to give tonic stimulation to the hard worked students, thereby avoiding educational fatigue. Not merely subjects of trade on industrial progress were introduced, but attempts were made to help the slow imagination of the country dwellers and by variety prevent that weariness of learning which always fell on those who had worked hard and been fed meagerly all their lives. Throughout the discussion on industrial and mental fatigue which was the feature of the British Association meeting, the ruling idea was evident that monotony of work, physical or mental, was to be avoided.

Bad Science Teaching.—Professor H. E. Armstrong, in the Educational Science Department, opened a discussion on the method and substance of science teaching and somewhat severely criticised the report of the Committee on the position of natural science in the educational system of Great Britain. The method of science, the scientific outlook, must be acquired if scientific knowledge was to be made of any avail. As in music and every other art, proficiency was to be acquired only by constant and laborious practice. The great majority of teachers had no understanding of the methods. They made no attempts to teach the art of inquiry, simply because they had never learned to be inquirers themselves. The prime need of the schools was men with some originality of mind.

Sir Richard Gregory spoke on the same subject. In the course of his remarks, which were also critical of existing methods of teaching science, he drew attention to an interim report of a committee appointed to examine the character, work and maintenance of museums in view of the importance attaching to the educational influence of museums. He pointed out that the most fully developed example of the use of a museum for educational purposes was that of the American Museum of Natural History, New York. He likewise praised the work done in the same field by the Pennsylvania Museum, the Public Museum of Milwaukee, the Carnegie Museum of Pittsburgh, the Field Museum at Chicago, and the U. S. National Museum at Washington. Sir Richard Gregory thought that England should follow the example of the United States so far as science teaching in its museums was concerned.

The Ministry of Health and Child Welfare.—The new British Ministry of Health, at the present time, mainly concerned in organizing itself, is engaged in gathering under its wing the various scattered health departments now administered by many different departments. Naturally the transfer of most of these services was a foregone conclusion, but not so obvious is the decision arrived at to transfer the Children's Division of the home office which deals with offenses by children and young persons. Although the work of the department is intimately connected with child welfare, it appears to be so, more on the moral than the medical side. Perhaps it was done to avoid overlapping and to secure coordination and concentration, which after all was one of the most insistent reasons for the foundation of a Ministry of Health.

Society for the Study of Inebriety.—An autumn conference of the Society for the Study of Inebriety will be held in the rooms of the Medical Society of London, Oct. 14, 1919. At the morning session the President of the Society will deliver an introductory address after which Lord D'Abernon will open a discussion on "The Scientific Basis of Drink Control." The question of alcohol will be considered from its scientific, quasi-scientific, and social aspects.

Mr. Thomas Pickering Pick, the well-known surgeon and anatomist, died on Sept. 7, last. He studied at St. George's Hospital, London, when Prescott Hewett, Timothy Holmes and George Pollock were members of the staff and obtained the first diploma in 1862. It was as an anatomist that Pick was best known. He was painstaking and absolutely accurate and probably the best editor of Gray's Anatomy. He also edited Holmes' "Principles and Practice of Surgery" for many years, one of the most popular manuals with both British and American medical students. Pick had a long connection with the Royal College of Surgeons, although he never succeeded in being elected president. He was appointed to the Board of Examiners in Anatomy and Physiology in 1876 and continued in the position up to 1894. In the same year he was appointed Hunterian Professor and delivered a series of lectures on Diseases of the Ends of the Long Bones in Children. In 1898 he gave the Bradshaw lecture and in 1903 became Vice-President of the College.

THALASSOTHERAPY OF CHRONIC RHEUMATISM.

(From Our Own Correspondent.)

GENEVA, Oct. 1, 1919.

As the treatment of chronic rheumatism by sea water is not extensively resorted to, it may be of interest to give a short account of The Marine Institute at Roscoff in Finistère, France, which for more than fifteen years has treated a large number of patients with very good results.

I here give the outline of one week's treatment for a rheumatic patient still in otherwise good health. The water employed is sea-water.

Monday—Morning: Hot douche. Afternoon:

Massage of lower limbs, followed by a hot affusion.

Tuesday—Morning: Vapor bath (or hot air). Afternoon: Massage of upper limbs followed by a hot affusion.

Wednesday—Morning: Hot douche. Afternoon: Hot sea-water bath.

Thursday—Morning: Vapor bath (or hot air). Afternoon: Massage of lower limbs followed by hot affusion.

Friday—Morning: Hot douche. Afternoon: Massage of upper limbs followed by hot affusion.

Saturday—Morning: Hot sea-water bath. Afternoon: Hot douche.

By massage is meant a kinesitherapeutic science comprising massage, passive and active movements, with or without resistance, gymnastics, etc., according to the stage of the treatment. When vapor baths are contraindicated on account of age or some cardiopathy, they are replaced by local vapor or hot air douches.

The ordinary duration of a course of treatment for chronic joint rheumatism is one month. Although the patients are given one day rest per week in order to avoid too much fatigue, this is quite enough. If a patient comes for a stay at the seaside of two of three months, excellent results without fatigue may be obtained by advising treatment every other day, in which case the treatment lasts two months, but it is much better supported by the patient.

Finally, if it is possible, a treatment of three weeks in June may be taken and two weeks in September will complete the cure for the year.

The patient does not usually remark any notable improvement during the first week of treatment and sometimes he feels more tired and his limbs are more painful. The sensitive joints are massaged and mobilized, sometimes with a certain amount of force. But after a few days improvement is manifest, the nocturnal pain subsides, and the articular functions progressively improve during the second and third week. During the fourth week the pain often returns and may discourage the patient, but he may rest assured that this is only due to the fatigue resulting from the treatment. The pain will disappear a few days after the completion of the treatment and the amelioration acquired will become manifest.

In mild cases the subject may be cured from the functional viewpoint and greatly ameliorated physically, but he should follow the usual diet of rheumatics and lead an active life. In the more inveterate cases the physical condition is improved, the joint movements are easier to execute, and the strength of the limbs partially returns. The patient is warned that at the end of the treatment he will experience a general lassitude for ten days or two weeks, and during this time he should rest and make only such movements as are necessary for the accomplishment of his daily needs. After this lapse of time a phase of progressive amelioration commences in both the general and local conditions. The ultimate results (two to three years later) are sometimes quite remarkable, especially when the patient leads an active life and follows the usual regimen of chronic rheumatism.

The contraindications for this sea-water treatment are not many. However, I would mention advanced age, especially if there are signs of cachexia or general organic wear which would prevent the development of a sufficient reaction; marked arteriosclerosis which would expose the patient to cardiac or cerebral accidents; uncompensated cardiac affections or when the phase of asystolia has been reached, finally, disturbances of the cerebral circulation and Bright's disease at the phase of cachexia.

2. The Differential Diagnosis of Hyperthyroidism by Basal Metabolism and Alimentary Hyperglycemia.—G. W. McCaskey presents a further discussion of basal metabolism and alimentary hyperglycemia with special reference to the differential diagnosis of hyperthyroidism from clinical conditions bearing some resemblance to it. He also points out the limitations of these laboratory methods, which, however valuable they may be, should always be regarded as subsidiary to the general clinical picture. There seems to be quite general agreement as to the causal relationship of overactivity of the thyroid gland to increased metabolism. In fact, it seems to have been proved that there is a close quantitative parallelism between the thyroid secretion and the metabolic rate, and that the estimation of the latter by means of the oxygen consumption may, therefore, be relied upon, with certain reservations, as an accurate index of the activity of the thyroid gland. The isolation and identification of thyrotoxin and its complete chemical study by Kendall, together with its physiological and therapeutic study by Plummer, have placed this enire subject upon an accurate, almost mathematical basis. These discoveries, in the opinion of the writer, have relegated to the domain of obsolete pathological conceptions the always dubious hypothesis of dysthyroidism, at least in so far as it refers to perversion, rather than a quantitative variation of thyroid secretion. From the strictly clinical aspects of the question one may confidently proceed on the following assumptions: (1) That the symptoms of hyperthyroidism and hypothyroidism are due to quantitative variations of thyrotoxin in the body cells. (2) That the fundamental phenomenon which dominates the entire clinical picture from cretinism to "Basedowism" is perversion of the metabolic rate. (3) That this metabolic rate has its absolute equivalent, in accordance with fully established physical laws, in the heat production of the entire mass of body cells. (4) That this heat production is essentially a process of oxidation and is equivalent to the quantity of oxygen consumed, the latter being regulated by, and dependent upon, the metabolic rate. (5) That it is now possible with the *comparatively simple* Benedict portable respiration apparatus to determine clinically the oxygen consumption over a sufficient period of time, say ten to fifteen minutes, with sufficient accuracy for all clinical purposes. (6) That if food metabolism is eliminated by twelve to fifteen hours' starvation (the usual normal condition in the morning), and the metabolism of voluntary muscular effort is eliminated by absolute rest in the recumbent position (one-half to one hour is sufficient), there remains only the energy output—the heat production—the metabolism of the circulatory and respiratory mechanism, with small and probably negligible additions for the phenomena of secretion and the intracellular chemical changes of the cells of the body while at rest, which is called basal metabolism. This so-called basal metabolism is very constant, not only in the same individual but in all individuals when calculated in *proportion to the area of body surface*, varying in health, in a large

majority of people, probably less than 10 per cent. from the average normal rate. The clinical estimation of basal metabolism is thus a very practical and reliable guide (and comparatively easy, although requiring the utmost care and accuracy) to the functional activity of the thyroid gland in health and disease, and without which thyroid disease cannot be adequately and scientifically studied. Before making a final decision as to the functional state of the thyroid, there are certain important limitations and reservations which must receive careful attention. The first and perhaps most important question is: What other causal conditions, aside from variation in thyroid activity, may produce the fluctuations of basal metabolism which form the basis of this clinical study? For while quantitative variations of the thyroid hormone produce these changes to an extent and with a promptness and certainty that nothing else can equal, it does not follow that other and independent factors exist with which one must reckon. In reality such factors do exist. Among these may be mentioned fever, severe cardio-renal disease, pernicious anemia, and age, all of which the writer discusses more or less in detail. With due attention to the precautions and exceptions suggested, the rate of basal metabolism must be regarded as an altogether dependable index of thyroid activity at the time of observation. With regard to alimentary hyperglycemia in its relation to hyperthyroidism the writer states: (1) That alimentary hyperglycemia following 100 grams of glucose is present in probably every case of thyrotoxicosis. (2) That it is rarely, if ever, present at the end of the first hour in normal persons, although it may have occurred at the end of about thirty minutes. (3) Its presence, therefore, in one hour and especially in two hours always indicates abnormal carbohydrate metabolism unless gastrointestinal function is delayed. (4) It occurs in latent, and of course in manifest, diabetes, in alcoholism, malignant disease, arthritis, and very probably in a considerable number of infections, acute, subacute or chronic in the same category with arthritis. (5) Before attaching a positive diagnostic value to alimentary hyperglycemia in suspected hyperthyroidism, these conditions and possibly others of which we are now learning must be excluded. (6) While its positive value can only be considered corroborative, its negative value in excluding hyperthyroidism is very great and probably exceeds 90 per cent. (7) In hyperthyroidism there is no constant direct ratio between its intensity and the height of the alimentary hyperglycemia, although in general the blood sugar values in severe cases are high. (8) Too much importance should not be atached to alimentary blood sugar values below 140 mgm. of sugar in 100 c.c. blood, although sharp lines of demarcation cannot yet be drawn.

2. Stone in the Kidney and Ureter from the Standpoint of the Clinical Surgeon.—A. J. Ochsner concludes that in the ureter the primary stone if it gets started, will usually pass. Secondary stones may be stopped by cicatricial contractions which may have been caused at some point by injuries due to the passage of one or more previous stones. A large proportion of stones of moderate size will pass spontaneously, or after dilatation of the ureter with bougies, the use of oil of glycerin injections, or one of the various methods of dilatation, preferably that of Lespinasse. In patients suffering from acute renal colic the use of morphin or atropin, hypodermically followed by the injection of 2 ounce doses of glycerin, with large quantities of distilled water, has seemed of value in aiding the passage of stones spontaneously, especially when the patient was immersed in a hot bath. The prophylactic measure of taking large quantities of distilled water seems to be effective in preventing recurrences. Sinuses remaining after pyelotomy or nephrotomy will frequently heal after injection with Beck's paste. The clinician who is alert for the discovery of renal or ureteral stone who takes into consideration the history and physical findings will rarely miss a correct diagnosis provided he confirms his diagnosis by careful urinary examination; by roentgenographic examination, with intensified shadows if necessary; by the introduction of ureteral shadow sounds, and by pyelography in doubtful cases. Dr. Ochsner gives the following points for differentiating diagnosis between tuberculosis and calculus: Hematuria without pain appears early in tuberculosis; hematuria with pain is constant in calculus. Pyuria without pain appears early in tuberculosis; pyuria with pain appears late in calculus. Pus is present in tuberculosis in excessive amount; in calculus it is minimal in amount. Pain in tuberculosis is diffuse, dull, constant; in calculus it is definite, sharp and intermittent. Chills in tuberculosis are common; in calculus they are rare. There is rise of temperature in tuberculosis, especially in the afternoon; in calculus it is rare. Tubercle bacilli in tuberculosis are sometimes present; in calculus they are absent. The ureter is thickened in tuberculosis, sometimes it is palpable; in calculus it is not palpable.

6. **Popularizing a Quinine Formula for the Treatment of Malarial Fever.**—Bruce Matne and Henry R. Carter state that the two most important problems of malaria yet unsolved are to find (1) the best means of determining the existence of malaria in man, and (2) the best method of eliminating it. The paper attempts to formulate a means to the latter end. The formula suggested does not take into account the question of symptomatology and the algid forms, nor are the severe cachectic cases included in the scope of the treatment suggested. It touches only the preponderance of the acute forms without peculiar atypical symptoms. The course of treatment provides for the application of a minimum of seventy-five days in the administration of 800 grains of quinine bisulphate. The formula is elaborated in a geometrical progression, consisting of four courses of 200 grains each. Forty grains are given daily for five days, 10 grains of quinine bisulphate being given four times daily. At the end of this period there should be no severe paroxysms, no chills, and only young rings and mature gametocytes in the blood. Twenty grains daily are then given for ten days. Then 10 grains are given for twenty days, and at this stage Fowler's solution or other tonic may be prescribed if indicated. Finally 5 grains are given for forty days. This stage is marked by the apparent recovery of the patient. At this juncture the continuance of the treatment should be strongly urged. At this time the microscope reveals only rapidly disappearing or disintegrating gametocytes. A systematic campaign of publicity emphasizing the necessity of this prolonged treatment in malaria would have far-reaching benefit both for the physician and for the patient.

2. **A Study of Hyperadrenalism; Its Influence in Producing Congenital Pyloric Hypertrophy and Subsequent Obstruction.**—George R. Pirie suggests that the spasm inducing hypertrophy of the pylorus is primarily due to hyperadrenalism before birth, and that other subsidiary postnatal causes determine the persistence or recurrence of the spasm. The condition, he argues, is due to a lack of balance between the secretions of the various endocrine organs in the process of their development and involution which may result in either a relative or an absolute hyperadrenalism. He believes that the balance of evidence indicates that the condition is congenital. It is true that the majority of cases first show symptoms at about the third week. It is equally true that, in many instances, the child forcibly ejects the first and every subsequent feeding. Moreover, at operation the hypertrophy is usually found to be so marked that it is difficult to believe it could have risen during extrauterine life. It must take a great deal longer to produce hypertrophy than many have hitherto thought, and one is forced to the conclusion that the cases under consideration exist from before birth, and that whatever influence has been at work must have existed for a long time. Keith has shown that both the pylorus and the medulla of the suprarenal gland become differentiated at about the third month of intrauterine life. Since excessive suprarenal secretion produces spasm in nonstriated muscles, this would allow plenty of time for spasm induced by any excessive suprarenal secretion to bring about hypertrophy. Keith also states that before birth the gland is larger than the kidney, and at birth may be the same size, and that it rapidly reaches its normal relative size. Sharpey Schafer, in his blood pressure experiments with adrenalin, noted that spasm of the pylorus was produced when he injected the secretion into the suprarenal vein. It is not claimed that adrenalin has a selective action on the muscles of the pylorus, for the same experiments showed that spasm was produced at many places in the gastrointestinal tract. The fact that untoward results of this spasm are noted so rarely in situations other than the pylorus is explained by the peculiar anatomical and secretory relations existing between the stomach, pylorus, and duodenum. The evidence seems to indicate that the spasm producing the stenosis must have been the result of some general physiological disturbance affecting all the orifices. It seems that the amount of hypertrophy present at birth is insufficient, except in rare instances, to cause the symptoms of obstruction. But there are certain conditions which will cause spasm after birth sufficient to complete the obstruction in an already stenosed orifice. There is sufficient evidence to justify the opinion that the two chief contributory causes of spasm, phimosis, and secretory inhibition, are directly associated with the congenital hypertrophy. In addition changes in the stomach, induced by the congenital pyloris stenosis hasten the formation of the vicious circle, and the perpetuation of the obstruction is due to the more rapid secretory arrest. Several instances of true congenital pyloric stenosis relieved of symptoms after circumcision are reported. The writer finds in this further justification for thinking that his theory of the pathogenesis of congenital pyloric stenosis is based on sound deductions. The writer urges the importance of a study of the internal secretory glands in relation to diseases of children, inasmuch as the physiology of children is entirely different from that of adults.

5. **Treatment of Septic Wounds by Ionization.**—F. W. Baker Young reports on the results of cases treated at a general hospital, at the request of Col. G. W. Crile, to demonstrate the effect of ionization in rendering wounds aseptic for delayed primary union. As the action of metallic ions is well known it was decided to try the effect of chlorine ions. An apparatus was devised for this purpose and experiments carried out. From these experiments the deduction is made that electrolysis with sodium chloride will inhibit the growth of *Staphylococcus aureus* and *albus* with a short exposure and a low current strength. Ten ma. given for ten minutes is sufficient to render a culture sterile. The deduction is also warranted that phagocytosis is probably stimulated by a small current passed for a short time. It was then decided to use sodium chloride in treating wounds as likely to cause less irritation to the tissues than metal ions. The average administration was 10 ma. for twenty minutes daily, the wound afterward being dressed with sterile gauze soaked in normal saline. The results in these cases led to the conclusion that ionization with chlorine or zinc does not possess any advantage over other methods for sterilizing a wound for the purpose of delayed primary suture. Cases of cellulitis show a marked improvement when treated with ionization, both in the relief experienced by the patient and in the final result, which in every case treated was extremely satisfactory, cicatricial contractures being practically unseen. One septic joint treated in this way recovered, indicating that the treatment is worth trying in similar cases.

2. **The Nature of Rabies and the Antirabic Treatment.**—Sir David Semple concludes his articles on this subject by a description of the various methods employed to immunize patients against rabies. He again emphasizes the importance of early treatment before the virus implanted in the wound by the animal which inflicted the bite has had time to reach the nerve centers, and the fact that if immunity has not been conferred by that time treatment is futile. He describes different methods of preparing antirabic vaccines with living virus either from the spinal cords, or from the brain, medulla, and spinal cords of rabbits which have died from rabies after inoculation with "fixed" rabies virus. In the "dried cord" method a living virus is not used until after the commencement of treatment by a dead or attenuated virus; but in the dilutation method, and in the method of drying the cords for a short time and preserving them in glyceria, a living virus is used from the outset. He describes his method of producing antirabic serum by immunizing horses to a high degree with rabies virus by which he produced a serum which was highly rabicidal when mixed with living rabies virus. In a mixture of one part of serum to three parts of a strong virus emulsion the virus was destroyed in a few minutes at room temperature. He used this serum hypodermically as preliminary to the ordinary treatment in badly bitten and late cases, his object being to create a passive immunity pending the acquisition of an active and more lasting immunity as the result of treatment. This preliminary treatment was used in 202 cases, but owing to the fact that the serum was followed by ordinary treatment it was difficult to say whether any real benefit was derived from the serum. The writer also describes his method for the preparation of a 4 per cent. dilution of *dead* virus in 0.5 per cent. carbolic acid in physiological saline solution. This is a dilution suitable for treatment purposes, and can be still further diluted if necessary. This vaccine retains its immunizing properties unimpaired for three months at least, and probably for a much longer period, when kept in a moderately cool place, and not exposed to light. The vaccine can be prepared in any well-equipped bacteriological laboratory, and by any bacteriologist skilled in the technic of the preparation of bacterial vaccines. From such a laboratory it could be sent to various centers for treatment without running any risk of interfering with its efficiency, and where any medical man with a knowledge of the administration of bacterial vaccines could carry out the treatment of patients. A comparison of the results obtained by this carbolized antirabic vaccine with the results obtained by other methods of treatment show a lower percentage of failures for the antirabic vaccine. Antirabic treatment is now being carried out in England with carbolized antirabic vaccine.

Book Reviews.

THE MEDICAL CLINICS OF NORTH AMERICA. Volume 2, Number 6, May, 1919. Index Number. Published bi-monthly. Philadelphia and London: W. B. Saunders Company.

THE concluding number of this volume of the Medical Clinics is devoted to contributions from the City of Baltimore. They are chiefly from Johns Hopkins, naturally, but include a good proportion from the University of Maryland School of Medicine. There is much in this number that will bear study. Barker's presentation of a neurological case is an excellent example of how one should proceed in neurological diagnosis. There are several papers on gastrointestinal topics that are very instructive. One especially gives details of the Sippy treatment of gastric ulcer, a treatment that has given especially good results. Hamman's introductory remarks to a discussion of diabetes are especially noteworthy. There are, in all, thirteen contributors to this number and the papers are, without exception, of rather unusual interest.

A TEXT-BOOK OF CHEMISTRY FOR NURSES. By FREDUS N. PETERS, A. M., Ph. D., Professor of Organic Chemistry, Hahnemann Medical College, Kansas City. St. Louis: C. V. Mosby Company, 1919.

WHILE it is essential that the nurse be more or less familiar with a certain amount of chemistry, it is not necessary that she understand the subject very thoroughly or spend much time upon it. Under the circumstances any course in chemistry, designed for nurses, must be given with a minimum of technical language and with a maximum of general information. This small book would make almost an ideal text-book for such a course. Not too long, it runs lightly over the whole list of elements, touches upon the carbon compounds, gives insight into formulae and the laws of gases and yet scatters throughout the text interesting bits of information relevant to the topic at hand. It makes interesting reading even to one familiar with chemistry and that is a severe test for any elementary work. It should be a valuable help in teaching. It is necessary to question one statement made by the author (page 164), that chloroform and ether are used mixed more often than ether alone. That is certainly not the case. While ether is certainly inflammable, one rarely hears of explosions taking place in the operating room.

CEREBROSPINAL FLUID IN HEALTH AND DISEASE. By ABRAHAM LEVINSON, B.S., M.D., Associate in Pediatrics, Northwestern University Medical School; Associate Pediatrician, Michael Reese Hospital; Attending Pediatrician, Mount Sinai Hospital, Chicago. With a foreword by Ludvig Hektoen, M.D., St. Louis: C. V. Mosby Co. 1919.

THE various procedures for the examination of the cerebrospinal fluid that are employed in modern laboratories have not hitherto been collected into one volume. Levinson's book will be all the more welcome because of the increasing frequency with which resort is had to the examination of this liquid and the great convenience in having all of the data in one place. Readers will find the information exceptionally complete. In addition to the ordinary routine tests which are applied, the book contains ample discussion of a large number of procedures which are not at all familiar, but which promise to have definite value. The sulphosalicylic mercuric chloride method is one of these. Beginning with an historical chapter, the author then discusses the anatomy and physiology of the cerebrospinal liquid and the best method of obtaining samples for analysis. He is a believer in lumbar puncture with the patient in the reclining position. He presents the characteristics of normal and then of pathologic fluids, devotes a chapter to the technique of the tests mentioned, discusses the findings in various diseases and finally gives a chapter to intraspinal treatment. He has obviously had a wide experience in his subject, his discussions are clear and his judgment good. The book should be an invaluable one, not only to laboratories, but also to many practitioners. The author uses the word "pellicle" to describe the filmy coagulum which forms in some pathological fluids. This seems an unfortunate choice of a term for the word means a film or scum forming on the *surface* of a fluid and its use is liable to lead to a misunderstanding. On page 191 he is made to say that the fluid in tuberculous meningitis contains 0.5 to 0.6 per cent of sugar, when he certainly means 0.05 to 0.06 per cent. In the chapter on technique he gives the old method for the preparation of colloidal gold solution, certainly a tedious and difficult one. It has seemed to us that the method of Lee is much more desirable both because of its simplicity and because it is more apt to yield satisfactory results. He fails to mention any method for the intraspinal administration of arsphenamine except that of Swift and Ellis. His observations on the formation of crystals from the cerebrospinal fluid are extremely interesting. It is quite possible that further research may yield information of value in this field. Altogether, the work is an interesting and important one and should find a large demand.

THE HEALTH OFFICER. By FRANK OVERTON, A.M., M.D., D.P.H., Sanitary Supervisor, New York State Department of Health, and WILLARD J. DENNO, A.B., M.D., D.P.H., Medical Director, Standard Oil Company. Philadelphia and London: W. B. Saunders Company, 1919.

IN their preface the authors state that this book contains the information which the average health officer must have in order properly to discharge his duties. This is a conservative statement. The work is exceptionally complete. Founded to a certain extent upon the practice in the State of New York, it is broadly worded so as to permit of application to conditions in other localities. The book begins with a discussion of the duties of the health officer and the laws under which he works. The communicable diseases are discussed and with them is considered briefly the subjects of bacteriology and immunity. Finally, the subjects of food, water, sewage, ventilation, hygiene, and sanitation are briefly but amply covered. The health officer, especially when situated in a small community, is or should be an educational center, not only to the laymen but also to the physicians of the locality, who often are far from being "up to date" in regard to bacteriological and epidemiological subjects. His position is one of great importance and wonderful opportunity for doing good in the broadest sense of the word. Every health officer and many others who are interested in the subject should have a copy of this book. The language is simple, the style attractive, the illustrations well selected, and the price small.

THE MEDICAL AND SURGICAL ASPECTS OF AVIATION. By H. GRAEME ANDERSON, M.B., Ch.B., F.R.C.S., Surgeon, Royal Air Force. With Chapters on Applied Physiology of Aviation by MARTIN FLACK, M.A., M.B., Lt.-Col., R. A. F., and the Aero-Neuroses of War Pilots by OLIVER H. GOTCH, M.B., Ch.B., M.R.C.P. (Lond.), Phys., R. A. F., and an Introduction by the Right Hon. the LORD WEIR of Eastwood, P.C., Secretary of State for the Royal Air Force. New York: Oxford University Press, American Branch, 1919.

THIS book is based on four years of experience with the air forces of Great Britain during the war and contains the conclusions derived from this active life. How to select candidates for aviation and a clear-cut discussion of the psychology and physiology of aviation follow a brief history of the development of the art. Methods of examination are not given in detail, but are referred to by their names. The discussion of the aeroneuroses is most important. In the chapter of surgery the author describes fracture of the astragalus as "aviator's astragalus" because of its frequency as a result of aeroplane accidents. Accidents themselves are described and pictured and their chief dangers analyzed. There is brief reference to "dope" poisoning. Of all of the works that have been produced as a result of the war, this is likely to lead in its application to peace conditions. We are assured that the aeroplane is to be an important factor in commerce and that flying will become increasingly common. If so, the lessons learned under the stress of warfare and expounded in this book will have fully as great importance in peace-time flying, and all medical men who will have anything to do with aviators will want to have reference to a copy of this work.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Twentieth Annual Meeting, Held at Atlantic City, June 6 and 7, 1919.

DR. DOUGLAS VANDERHOOF OF RICHMOND, VA., IN THE CHAIR.

(*Concluded from page 630*)

Influenza and After.—Dr. THOMAS F. REILLY of New York made this presentation.

The Present Status of Prophylactic Vaccination Against Influenza.—Dr. F. E. STEWART of Philadelphia, presented this communication. (See page 681.)

Pneumonia in the Army Camps.—Major RUSSELL L. CECIL, M.C., U.S.A., of Camp Upton, spoke on this subject. He said that it was universally recognized that during the recent epidemic the high mortality was due to pneumonia. There were two ways of approaching the problem: (1) to prevent influenza; (2) to prevent the pneumonia. One did not know what caused the influenza, but one was justified in trying vaccine. Vaccination was tried at Camp Wheeler with 3,000 men; one injection was used. There were just as many cases among vaccinated as among unvaccinated. An attempt was then made to prevent complications by using pneumococcus vaccine. There was no objection to putting other organisms into the vaccine. Three strains were tried. With mice the larger the dose given the better the immunity. Army lipovaccine was used with strains I, II, and III pneumococci. The men were vaccinated from the train, and had been exposed before the lipovaccine could get in to do its work. It took ten days to produce immunity. At Upton there were 173 pneumonias among unvaccinated and 17 among vaccinated. The pneumonia was type IV, against which the men had not been vaccinated. It would seem that influenza so lowered resistance that the men could not oppose the pneumonia infection. Experiments on monkeys, animals extremely susceptible to pneumonia, were disappointing so far. The animals got pneumonia, but the vaccine seemed to protect from fatal pneumonia. One got more agglutinins with the saline vaccine, but more protection with the lipovaccine. Perhaps one was not justified in reasoning from monkey to man. in monkeys the vaccine was not enough to protect. If one could get people to take living pneumococci, one could guarantee immunity.

Treatment of Influenza and the Pneumonias Incident Thereto.—Dr. JACOB DINER of New York read this paper (see page 685).

The General Treatment of Influenza.—Dr. NOBLE P. BARNES of Washington, D. C. presented this communication (see page 686).

The Control of Epidemic Influenza in a Large Institution.—Dr. HORATIO C. WOOD of Philadelphia read this paper (see page 689).

Lipovaccines.—Dr. A. PARKER HITCHENS of Indianapolis read this paper (see page 692).

Influenza in the Army Camps.—Col. THOMAS S. JACKSON opened the discussion on this subject (see page 696).

Dr. M. HUNTOON of New York said that the use of vaccine in any diseases rested on two grounds: (1) knowing the causative agent; (2) the empirical ground that its use produced results. With both reasons, one felt safer. Influenza plus pneumonia constituted two distinct diseases, with the initial cause unknown, although evidence was somewhat in favor of the Pfeiffer bacillus. Deaths were caused by secondary pneumonias. The pneumococci were mouth organisms, except where they took on epidemic types. The majority of pneumonias were caused by *Streptococcus hemolyticus* and type IV pneumococcus. It was perfectly logical to attempt to vaccinate against secondary invaders. The use of multiple vaccines had been shown to be experimentally valid. It was logical to use shotgun mixed vaccines in these conditions. Evidence as to results was contradictory. In the Western cities where the Rosenow mixed vaccine was employed, there was a definite decrease reported in the number of pneumonias following influenza, and particularly in the deaths. In Louisville, there were 1,800 cases carefully watched, and only two deaths. The speaker said he was sorry to hear the unkind aspersions of Dr. Barnes against the influenza bacillus, which was a friend of his. Dr. Barnes had said that pneumococci and streptococci were more often found, but, with improved technique, it would be found that the influenza bacillus was the greatest common denominator. Ewing said it could be found in any lung if one looked long enough. Duval found it in every case but one, of 60 autopsies, so that it was a very common organism. Cole regarded it as the most important secondary invader. Some unpublished work showed that the toxemic symptoms noted could be produced by injection into experimental animals of the toxic product of the *B. influenzæ*, which had selective action for the lung, causing intense congestion with hemorrhage into the alveoli. These conditions produced all sorts of secondary infections of the lung. Injection of *B. influenzæ* into the cranial cavity was followed by hemorrhagic pneumonia in rabbits. Animals with sublethal doses, afterwards picked up streptococci, and died from streptococcus pneumonia, The speaker said he did not think one could yet rule out the influenza bacillus. It was the most important primary secondary invader.

Dr. C. E. DE M. SAJOUS of Philadelphia said he had been very much interested in this discussion. He had had the opportunity to do some work on these lines. He was attached to the Emergency Hospital No. 2 of Philadelphia, where the worst cases were sent from the dark corners. The losses there were 7 to 8 per cent. All the remedies and methods were tried by the 24 men assigned to attend to the patients. Dr. Sajous called his staff together and said that he had been a pupil of Pasteur and knew something of bacteriology. No remedy was to be given, without his knowledge of it. Great care must be exercised in treatment. The boys had to be kept warm, a little whiskey and water was given, coal-tar products and salicylates were avoided, a little quinine was used. The mortality was very low on this treatment. There was not so much flaw in knowledge of the causative bacillus, as there was in the way in which it caused trouble. It was possible that the sympathetic nervous system was the victim of the Pfeiffer bacillus. Probably the digestive ferments were the most active protectors of the organism. The leucocytes had a great deal to do with the protective activity, through the ferments that they transmitted to the cells in general. In the biological laboratory it was proved that ferments varied according to temperature. By lowering temperature one to four degrees there was deficient activity of the ferment. The condition of the camps and cantonments caused the boys to be more exposed to cold than normally. Many deaths had been due to exaggerated fresh air notions prevalent in this country. Many deaths were due to low temperature because the proteolytic activity of the ferments was thereby lowered. Fever raised the proteolytic activity to defend the organism. This had formed the basis of Abderhalden's work, but the speaker said he had published these views six years before.

Dr. E. ZUEBLIN of Cincinnati said that in regard to the physical signs and after care of pneumonia, he agreed with Drs. Diner, Reilly, and Dawes that manifestations were found at the angle of the scapula at the site of the pneumonic complications. There were many rales due to edema. On the sterescopic plate residual signs of pneumonia were found. These persisted a long time and might be a reason why the patient did not recover. Dr. Sajous had mentioned ferments; an interesting report was published in Cincinnati giving the favorable results of a liquid farinaceous diet, with frequent alkalis. He thought proteolytic action was helped by proper supplies of fluid, which they were afraid of on account of the pyrexia. He thought vaccines were commendable. They gave the Rosenow vaccines in infectious cases. This avoided a high mortality if given in time, and results were more favorable than anticipated.

Dr. ROUSEL of Philadelphia said that those who had passed the 1891 epidemic knew that there was a difference in mortality statistics of uncomplicated influenza and the complicated type. Uncomplicated influenza had very slight mortality. In the past epidemic patients often died before pneumonia was diagnosed. Men were waiting for classical signs upon which to base

the diagnosis. A fair proportion of the influenza pneumonias (12 per cent.) showed kidney involvement. Six per cent. had acute nephritis with marked albuminuria. Many cases probably escaped notice as the work was so overwhelming that proper observations were not made. In regard to vaccines, they were of use in selected cases. Dr. Kolmer was ill himself in the height of the epidemic, and Dr. Rousel tried to make vaccines for him. A similarity of organisms was noted. Pneumococci I, II, and IV; streptococci, staphylococci, *Micrococcus catarrhalis*, and the Pfeiffer bacillus. He did not feel that the Pfeiffer bacillus was the chief organism, but virulence of the whole group was increased by trench life. The civil population was underfed and overworked,—conditions which would imply the acme of destruction. Forty cases of pneumonia in women were treated by the speaker, with vaccine, in the first days of the disease. The mortality was 11 per cent. His total mortality of all cases was 25 per cent. In regard to drugs: alkalis were useful. Bicarbonate of soda solution, intravenously, by rectum, or internally was useful. Adrenalin, pituitrin, atropine, were useful in certain cases. A large amount of sleep and rest was essential. Many men would hardly ask the nurse how the patient had slept, but this was important. Morphine surphate at night could be given to ensure sleep. This should not be overlooked. There was an abdominal type of influenza, with earmarks of typhoid, coated tongue, enlarged spleen, etc. There was also a nervous type of case. Encephalitis was an influenzal sequel. It was cerebral irritation rather than true inflammation.

Dr. F. M. POTTENGER of Monrovia, Calif., said that in regard to tuberculous influenza there were rather definite grounds for believing that there was a cetain nonspecific immunity. He did not think the tuberculous patient was susceptible to influenza. Among 100 patients there was not a single case, although many of the friends had influenza, the patients did not. There was no quarantine, but care was taken. As regards cold air, there was nothing to be gained by subjecting the patients to cold. They did not require an absolutely equable temperature. It could be much lower than 72°. In the first number of *Modern Medicine* there was a very interesting article by Huntington of Yale on the effect of climate on civilization. In regard to changes of temperature, a marked variation between morning and night was beneficial to patients and acted as a stimulus, as long as the body cells reacted well. In regard to diagnosis, Dr. Pottenger said he did not have the opportunity to see cases in general practice, but in 1,800 cases seen at Camp Travis he was able to make an early diagnosis by the auscultatory method. By studying the reflex action from the lung one had an opportunity to determine whether the lung was diseased. With reflexes from the lung there was spasm and increase tension of the cardiac and shoulder muscles. A number of the post influenzal cases had increased mediastinal glands. One could palpate heart, lungs, liver and other organs by touch, one did not have the resonance of the entire chest wall to interpret. Experimental work at Harvard had shown that with the vagus cut, dogs could manage to breathe. Belladonna decreased the action of the vagus, and so should adrenalin because it stimulated the opposing sympathetics. Dr. Reilly had observed that where the hylus was involved, the reflex was shown in the interscapular region by atrophy of the muscles. If the pain occurred lower down, it was from the pleura. There was no pain from the lung over the spine and scapula. The pain from the lung was in the shoulder and neck. The pain in angina was from the cervical portion of the cord.

Dr. DOUGLAS VANDERHOOF of Richmond said that no one had convinced him of the value of vaccines in a disease that did not confer immunity in the body. Influenza seemed to predispose to other attacks. There might be danger in producing a negative phase by vaccine, thus subjecting the individual to increased sensibility. The speaker said he had worn a face mask of 4 thicknesses of gauze, right through the epidemic, when among infected persons, and it had certainly afforded protection. Dr. Wood's point as to the isolation of patients in separate rooms was very valuable. Certainly patients in private rooms did better than those in wards and cantonments. Prompt use was made by the speaker of the cubicle system. He felt that the high mortality was due to enforced congregation of the cases, with subjection to mixed infection.

Dr. REILLY, in closing, said that he had noticed one sign in patients with even mild influenza. They had enlargement of Steno's duct, with redness of the tip of the tongue, which stuck out like a cock's comb. Nausea was a distressing feature in the early part of the epidemic. This was well controlled with 3 to 5 grs. of chloral. Sajous' statistics of the epidemic of 30 years ago showed that the disease was different in different localities.

Dr. HITCHENS, in closing, said that experiments on a large scale had not shown a negative phase in vaccination. No harmful results had been noted. With regard to the point that the disease did not confer immunity, and therefore was not helped by vaccines, this phenomenon could be perhaps explained by analogy. Staphylococcus infection in boils did not produce an immunity, yet was greatly helped by vaccines. Bacteria might be so located with regard to the tissues that had to do with production of immunity, that the bacterial protein might not come in contact with the moiety that would be stimulated. Bacteria might be too far apart to stimulate production of immunity, but when bacteria were put into healthy tissues, active immunity was produced, which was effective in such infections as pneumococcus and staphylococcus. Wright, as a result of his work in S. Africa, concluded that one could certainly immunize in infections that did not of themselves produce immunity.

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-fourth Annual Meeting, Held in Atlantic City, N. J, June 14-17, 1919.

(*Concluded from page* 611)

A Study of Bladder Function.—Dr. ARTHUR H. CURTIS of Chicago drew the following conclusions: "(1) Failure to catheterize the paralyzed bladder is followed (in rabbits at least) by back-pressure of urine, which is exceedingly destructive to kidney tissue. Associated urinary tract infection is frequent. (2) Irregularly performed catheterization for retention of urine is unsatisfactory. Patients so treated are subjected to such dangers as accompany passage of the catheter and, at the same time, are rendered liable to accumulations of infected stagnant urine. (3) Carefully managed catheterization of the bladder, which fails to empty spontaneously, yields excellent results; the catheter should be regularly passed often enough to prevent vesical distention, and its use must be persisted in until daily tests show that residual urine is no longer present."

Value of Repeated Small Blood Transfusions in Blood Stream Infections.—Dr. JOHN OSBORN POLAK of Brooklyn, New York, read a paper on this subject in which he drew the following conclusions: "(1) After the bacteria have gained entrance to the blood stream, the cellular elements of the blood are rapidly destroyed. The heart, liver, spleen, and kidneys show definite pathology, and acidosis develops. (2) Small repeated blood transfusions increase the cellular elements, stimulate resistance, raise the blood pressure, and hence add to the natural defense."

Age Distribution and Age Incidence in 500 Cases of Cancer of the Uterus.—Dr. REUBEN PETERSON of Ann Arbor, Mich., drew the following conclusions: "(1) The maximum age distribution in 500 cases of cancer of the uterus is at the age period 40 to 45. (2) Between the ages 35 and 65 occurs 82 per cent. of uterine cancer. (3) The young female is not immune to cancer since 7 of 500 cases or 1.4 per cent. occurred between the ages of 20 and 25. (4) Uterine carcinoma below the age of 20 is exceedingly rare, but it does occur in an appreciable percentage of cases between 20 and 25. (5) The cervix was the seat of the disease in 6 out of 7 cases occurring between 20 and 25. (6) Maximum number of cases of carcinoma of the cervix is to be found in age period 40 to 45. (7) In the present series fundal carcinoma was found in an un-

usually large percentage of cases, 94 out of 500, or 18.8 per cent. (8) Maximum number of cases of adenocarcinoma of the fundus is to be found between 55 and 60, fifteen years later than in squamous cell of the cervix, which is 40 to 45. (9) Adenocarcinoma of the fundus is not a disease of early life, there being in the present series only 3 cases out of 94 below the age of 35. (10) From the analysis of this series and from the statistics of other writers it is fair to assume that from 10 to 15 per cent. of uterine carcinoma is located in the fundus. (11) A large proportion of the 500 cases of uterine cancer was squamous cell carcinoma of the cervix, 369 in all. (12) In contradistinction to carcinoma of the fundus 23.5 per cent. of squamous cell carcinoma of the cervix is found in patients under 40. (13) Practically 50 per cent. of the 369 cases of squamous cell carcinoma of the cervix occurred between the ages of 40 and 55. (14) Adenocarcinoma of the cervix is much more rare than the two other forms, 37 out of 500 cases. (15) The maximum number of cases occurs in age period 40 to 45. (16) Between 20 and 40 years of age there were 30 per cent. of the 37 cases of adenocarcinoma of the cervix. (17) The age incidence of carcinoma of the uterus at different age periods is determined by the following: Ratio for age period N =

$$\frac{\text{percentage of carcinoma for age period N}}{\text{percentage of population for age period N}}$$

(18) The maximum age incidence for carcinoma of the uterus is at age period 55 to 60; it declines rapidly from this age period to the period 70 to 75. (19) The greatest age incidence for adenocarcinoma of the fundus is the same as that of cancer of the uterus as a whole, age period 55 to 60. (20) The highest carcinoma incidence in carcinoma located in the cervix, in squamous cell carcinoma of the cervix and in adenocarcinoma of the cervix is at age period 50 to 55. (21) After each age period of greatest carcinoma incidence is reached there is a sharp decrease in incidence, demonstrating the incorrectness of the statement that the age incidence of carcinoma increases with the age period."

Further Observations on the Radium Treatment of Uterine Cancer.—Dr. HAROLD BAILEY of New York stated that practically all of the cases that had a complete radiation of the local lesion and the lymphatic and other involved tissue in the parametrium passed through a period of improvement. In all but the more advanced conditions this improvement consisted of a disappearance of the ulceration, a lessening or entire disappearance of the discharge, a gain in weight and general improvement of health. Undoubtedly patients' lives were lengthened. A number had some slight degree of rectal irritation, beginning a week or ten days after the treatment, and lasting two or three weeks. A few had a fibrosis of the pelvic connective tissues, especially at the bases of the broad and uterosacral ligaments. Where this bridge of tissue constricted the rectum to any marked degree a fistula would form above and communicate with the vault of the vagina. As mentioned by Burnam, when this did occur all pain was relieved and the patient gained at once and, in his opinion, did not have nearly as unhappy and as miserable a life as might be expected. After a longer or shorter time of well-being following the treatment, many of the cases had further development of cancerous tissue behind the vault of the vagina. In the effort to save these patients that had a retrogression after six or eight months, he had pushed the radium treatment of the parametrium, both by vaginal and by surface radiation to the highest limits of safety, and had thereby caused in many who appeared to be free from cancer, various types of pelvic sclerosis, both mild and severe. He had felt that it was wise to recede somewhat from the massive dose given by the bomb applicator. This dose now was actually in the neighborhood of three-fourths of the maximum; the dosage in 1917 being about one-half the maximum. The method in use permitted of the entire treatment being given in a 48-hour period, and with only moderate discomfort to the patient. The local slough and signs of irritation in the vault of the vagina, seen so frequently in using the older method, was now lacking in most of the cases. The most spectacular results in the entire series were those of the fourth Wertheim operations, which followed a month after the radiation. In three of these, no cancer cells were found in the uterus or parametrial tissue that was removed; and in the fourth case only a few markedly hydropic and degenerated cancer cells were present in the parametrium. It must be admitted that in these cases, at least, the radium caused the tumor cells to disappear even more thoroughly than ablation could have removed them. If such results could be looked forward to with any degree of regularity, then the very reason for the operation would cease to exist. It should be a very simple problem to settle, for all time, the relative merits of these procedures. Twenty-five consecutive cases, well controlled, would show how dependable were the results of this type of radiation. Without the removal of the uteri of some such number with a plan carefully followed, there would always be uncertainty; for even in the cases of this series, where there was every reason to believe that the patient would be restored to health, after a year he found that one was dead, and two had massive involvement of their pelves that was apparently cancerous. The question at issue was not the cure, but whether radiation would cause the permanent disappearance of cancer cells, from a region as wide in its limits as that area that would be removed by the most complete hysterectomy of the Wertheim type. From the results in the uterine body cancers, it would appear to be necessary to remove the uterus after a preliminary radiation, or where this was inadvisable to radiate the entire pelvis as completely as was done with a cervical tumor. The results in the recurrent cancer following a hysterectomy were very promising. It should be understood that it was as important to radiate these cases immediately after operation as it was to operate early in the course of the disease. Taking only the years up to 1918, there were 26 per cent. of the recurrent cancer cases still living; 59 per cent. of this type of the year 1918 were still living. Of course, this number would drop tremendously during the next year; and it only illustrated the point mentioned above, that so many of the cases have a temporary improvement and retrogression. Over 60 per cent. of the cases treated as a prophylaxis, against the return of the tumor following a hysterectomy, were still free from the disease, but as most of these were treated in 1918, a year or two more must pass before any conclusions might be drawn. So great had been the palliation from the radium that it might be said that no uterine cancer case received proper treatment without thorough radiation of the tissues of the pelvis.

Tumors of the Bladder in Women, Their Diagnosis and Treatment.—Dr. HOWARD A. KELLY of Baltimore began his paper with a brief historical review, recalling the days when it was not uncommon for the specialist to examine the bladder by boring his finger in through the urethra, an act followed commonly by incontinence. With the cystoscope all this became changed. The speaker insisted on the great advantages of the open air cystoscope in diagnosis and treatment. Its simplicity was in its favor and there was no murky medium to be changed, and with one instrument it was possible to sweep rapidly over all the wall of the bladder and note every lesion. He then spoke of the importance of utilizing the natural landmarks as well as an artificial division into hemispheres, easily adopted from the viewpoint of the internal orifice of the urethra. Using the end of the speculum as a measure and an observation of these landmarks, the first step was to plot out all areas of disease and note them on a simple chart. This gave plan and precision to the treatment. Malignancy in bladder tumors was not always to be determined from the microscopic standpoint. Some tumors which were classified as malignant by the pathologist were clinically benign and vice versa. An ulcerated and infiltrated base was the clinical test of malignancy. The treatment was occasionally by excision, but, as a rule, by fulguration and radium. Fulguration did well in some cases but often failed. Radium was applied in the form of emanation on the end of a sound, introduced and applied directly to the growth through the

open cystoscope, or held a little way from it. A proper dosage was 250 milligram hours, over an area 2 x 2 cm. per month. If one was using 1,000 milligrams, then this meant a total application of 15 minutes, and if this was divided up into four treatments as seemed best, then each treatment lasted only about 4 or 5 minutes. In this way, many cases had apparently been cured, including even those which were malignant and infiltrative.

President's Address: Gynecology as a Specialty.—Dr. Franklin H. Martin of Chicago delivered an address on this subject in which he drew the following conclusions: "(1) Gynecology, as an exclusive specialty, is justified under the formula," a specialty is justifiable when a portion of the human body, physical or functional, is sufficiently distinct and important to justify a group of practitioners in devoting their whole time to the consideration of its diseases, if by devoting their exclusive time to such special diseases, it is made apparent beyond a doubt that such attention is justified by improved results. (2) Gynecology requires for its successful pursuit practitioners who recognize in its possibilities a specialty sufficiently broad and sufficiently congenial to their tastes to be willing to practise it exclusively. If gynecology requires for its successful pursuit the addition to it of the routine practice of obstetrics or the surgery of the upper abdomen of women, it cannot be ranked as a successful specialty. (3) The status of gynecology must be re-established by convincing the faculties of medical schools and the medical staffs of our principal hospitals that departments of gynecology are necessary. (4) Gynecologists as medical school teachers and as heads of hospital staff departments must emphasize the importance of their specialty by an exhibition of and teaching of their diagnostic methods, and a demonstration to their students and confrères of the importance of their medical and surgical results. (5) Discussions of relative value and relation of specialties should be abandoned and in their place should be established the *esprit de corps* of gynecology, and its devotees should establish a practical research program that will more definitely place the specialty of the surgical and medical diseases of women on a firm foundation."

A Report of the Work of the Detention Home for Women.—Dr. Palmer Findley of Omaha stated that the following were the points of special interest gained from his observations in the management of these cases: (1) More than half the cases were drug addicts and all were social derelicts. As a moral problem, the work was most discouraging. (2) It was doubtful if the public was as yet ready for this reform movement. Public sentiment was as yet not crystallized, but much had been accomplished in educating the public, and there was no doubt that the Public Health Service would perform an inestimable service in continuing the propaganda that had been so effectively pursued in the past year. (3) In a total of 275 cases admitted to the institution all but 8 were gonorrheic, 70 per cent. were also syphilitic, though only one in ten showed any clinical evidence of syphilis. (4) The complement fixation test for gonorrhea was of no practical value. (5) A single negative smear had no significance. In only 30 per cent. of the cases, which ultimately revealed the gonococcus, was the organism found in the first examination, and in isolated cases the gonoccocus was not revealed until the eighth, tenth, and in one instance the fifteenth, successive daily examination. (6) He was impressed with the low percentage of tubal infections in the chronic cases. In only 2 per cent. did the tubes reveal any evidence of infection in the clinical examinations. (7) Gas anesthesia, permitting the cervix to be dilated and the endometrium to be swabbed with formalin and iodine solutions shortened the period of detention about 50 per cent. The average period of detention had been ten weeks, but with the aid of gas anesthesia we shortened the period of detention from four to six weeks.

Are the Operative Procedures Done for Dysmenorrhea and Sterility Justifiable in the Light of Developmental Study?—Dr. Frederick C. Holden of Brooklyn, New York, drew the following conclusions: "(1) Operative procedures alone give a small percentage of successes. (2) Operative procedures sometimes add a troublesome pathological condition of the genital organs to the symptom-complex of dysmenorrhea and sterility. (3) The only intelligent method of studying the activity of the spermatozoa is in their relation to the female secretions. (4) Ductless gland therapy is at present in its embryonal stage. While the writer fully appreciates the dangers of the indefiniteness of this therapy, he does feel after careful consideration of a series of cases, of which those quoted are a type, that further experience with endocrines will tend to clarify our present position in regard to the treatment of dysmenorrhea and sterility."

The Relation of Preventive Medicine to Gynecology.—Dr. Henry P. Newman of San Diego stated that the gynecologist, working in the new medium of standardization, could come before his colleagues of the related specialties and lay emphasis on those points in which he felt their cooperation was vital in his work His own researches, fortified by the statistics of hospitals, permitted him to show to what degree the lesions he handled were due to causes outside his domain in practice while well within his province of theory. For the most part, he knew that he had to deal with the results of errors and neglect in the development and in the parturient periods and with infection. He must, therefore, ask of internists, family physicians and of pediatricians, intensive efforts towards the control and safeguarding of the growing girl. Each time that an infantile uterus, with its train of subsequent evils, presented in an overworked school teacher, artisan, or student, or barren wife, he must make to those other specialties a plea for the more thorough supervision of girlhood, and a campaign of effort towards elimination of the evils in our social and educational system which intensively cultivated the mind while destroying the body. And when he said "destroying the body," it was unfortunately not in a spirit of sensationalism; it was a reference in cold blood to the already widely circulated reports of some of our leading authorities in obstetrical science who agreed that the new type of woman, appearing as the effect of overcivilization, was no longer fit for maternity. "Indoor life and nerve tension" having prevented normal functional development, they announced that it was now better that "the delicate nervous woman be delivered by cesarean section than be subjected to the ordeal of labor." It was now that we, as members of an organized specialty, must turn from the laboratory and clinic for the moment in our investigations of disease and join forces with all other medical organizations and plan movements for the study and promotion of preventive measures. Instead of making our supreme effort the giving to the delicate, nervous, incapable mother, a child by the easiest surgical method, let us take up the work of giving the children yet to be born their first right, the staunch and stalwart mother to whom her normal labor shall be an expected and a remembered blessing. As gynecologists we could offer the most comprehensive program dealing with the health of women, and immediate and full cooperation with other specialties on our part would result in as widespread and momentous effects as those we had already alluded to as following the campaign against venereal diseases in our Army. And the need was bringing this emphasis, not as an indictment of the past, but as a legitimate outgrowth of all past efforts.

Pseudomyxoma Peritonei.—Dr. James E. King of Buffalo said that pseudomyxoma peritonei presented a rather constant clinical and pathological picture, although the exact etiological factors that produced the peritoneal changes were still more or less in dispute. There was general agreement, however, that practically all cases resulted from the contact upon the peritoneum of the colloid contents of ruptured pseudomucinous cysts. There were three principal theories which had been proposed to account for this effect of the pseudomucin of these cysts upon the peritoneum. The first held that it caused a chronic productive inflammation associated with myxomatous degeneration. The second was the implantation theory which viewed the pathology as a result of implantation upon the peritoneum of cells derived from the ruptured cyst wall. The third theory regarded the process solely as a reactive peritonitis produced by the mechanical and chemical effect

of the unabsorbable colloid material. The diagnosis of pseudomyxoma peritonei might in some cases be made with reasonable certainty. The dull pain, with rapid and irregular enlargement of the abdomen was suggestive. The encysted collections were usually flaccid and gave a distinct fluctuation even though the pseudomucin were very thick. There would always be evidence of a pelvic collection which was diffused. In addition to the physical signs, the loss of weight and general appearance of the woman weighed strongly in arriving at a diagnosis. The prognosis was usually unfavorable. The course of the disease was essentially one of malignancy. With a process reasonably localized, or if by early operation after rupture, the cyst and its contents could be completely removed, recovery might be hoped for. Treatment was only palliative in advanced cases. The cystic collections might be temporarily relieved by surgery. In one case of the writer's a few months after the first operation a second was done, and following this the abdomen was exposed to the *x*-ray in the hopes that the process might be stayed. The treatment was carried on at the State Insitute for the Study of Cancer. Apparently the treatment had no effect. Possibly earlier it might have been useful, and it would seem that in such cases it might be tried. The speaker concluded that pseudomyxoma peritonei was due to the reaction of the peritoneum to pseudomucin. The pathology consisted of a proliferative inflammation of the peritoneum with the organization of colloid material on the peritoneal surfaces. In the majority of cases it was a progressive process and resulted fatally.

Rupture of the Deep Epigastric Artery as a Clinical Entity, with the Analysis of a Case.—Dr. EDWARD A. SCHUMANN of Philadelphia said that the rupture of an artery, whether traumatic in nature or the result of disease of the vessels' walls was ordinarily followed by the general and local phenomena accompanying hemorrhage. In the case of certain vessels, however, there developed a well defined and distinctive chain of events, due either to the anemia created in certain tissues, or, more commonly, to the pressure exerted by the growing hematoma upon contiguous structures. The definite symptom-complex following rupture of the middle cerebral artery might be instanced as the most common and striking example of such cycle. Traumatic rupture of the deep epigastric artery, though of infrequent occurrence, might be followed by so complex and yet so definite a series of sequelæ that the pathological and diagnostic details might properly be grouped as a clinical entity, reasonably sure to present after the occurrence of such an accident.

A Floating School of Tropical Medicine.—The *Medical Times* of London states that a very interesting proposal, which should claim the earnest attention of all workers in tropical medicine, both in this country and America, was made by Dr. Louis Sambon in a lecture delivered recently before the Royal Society of Medicine, London. This in brief is the establishment of a floating school of tropical medicine. It is suggested that a specially equipped ship containing the necessary apparatus and laboratories should be taken from one tropical area to another. The students would thus have opportunities of investigating the diseases in their natural habitats. The medical men resident in these out-lying areas would also benefit by these visits, for they are now frequently unable to keep abreast of current medical literature and much good work done by them is at present unrecorded.

Energetic Action Needed to Control Typhus.—The Interallied Medical Commission, which recently returned to Paris after an expedition to Poland, reports that energetic action is necessary to prevent the spread of typhus and other epidemic diseases to western Europe and America. Col. Hugh A. Cummins, Assistant Surgeon General of the United States Public Health Service, who is chairman of the commission, states that the epidemic of typhus continues despite summer conditions and that fresh cases are constantly being introduced from the East by refugees, prisoners of war, and repatriated persons. The Polish Ministry of Health and the army medical service are carrying on an active campaign against typhus, but personnel, supplies, and hospital accommodations are insufficient to cope with the situation. Relapsing fever, typhoid, and dysentery are also prevalent in Poland and more severe epidemics are anticipated this winter.

Influenza in British India in 1918.—An account of influenza in British India is to be found in a recent number of the *Office International d'Hygiène Publique*. We find here the final laying of the ghost of any kinship between influenza and the plague, for while the same provinces were ravaged by the two affections—the plague being endemoepidemic, while influenza came and went quickly—there was never the least token of any relationship or identity between the two. Influenza ravaged the plague-ridden districts and took a huge toll among the plague survivors, and at no time was there any confusion between the two. In India, as in most other countries, there were two quickly succeeding waves, the first of which was mild in character. There was striking evidence that the mild wave could immunize against the malignant epidemic which followed. The Indian pandemic seems to have been exclusively a pneumococcus infection. The disease first appeared in Bombay early in June, and the mortality was not striking. It was even milder in Calcutta and Madras, where it appeared soon afterward. It was not until September and October that the pandemic appeared in malignant form. Various theories as to its origin prevailed. There was a suspicious epidemic in the Tana district before its appearance at the seaports, and also a rumor that the first cases in Bombay had come from Mesopotamia.

X-RAY FINDINGS WITH THE DELINEATOR IN CARDIOSPASM.*

BY MAX EINHORN, M.D.,
AND
THOMAS SCHOLZ, M.D.,
NEW YORK

A DEFINITE clinical diagnosis of cardiospasm was rarely made, and usually only by experienced specialists, prior to the discovery of the roentgen rays. Soon after the beginning of the roentgen era, however, and especially after the introduction of the contrast meal method, the alimentary tract in general, and the esophagus in particular, became accessible to direct observation under the fluoroscope, and pathological conditions of the esophagus, formerly considered rare and difficult to diagnose, were found to be quite common and their diagnosis usually easy.

The first roentgenological reports on findings in cases of cardiospasm were published as early as 1897, by Doyen of Paris and Rumpel of Hamburg. Later on, with the improvement of the roentgen-ray instrumentarium and the resulting rising interest in roentgen-ray work of the alimentary tract, the literature on esophago- and cardiospasm became gradually quite abundant.

The roentgenological evidence in cases of cardiospasm is quite definite. The more or less complete constriction of the cardiac end of the esophagus, the dilatation of the organ, the abnormally strong peristalsis, and even antiperistalsis, the sudden cessation of the spastic contraction at times, especially

on application of antispasmodics, and all this observed directly by means of the fluoroscope, make the picture so characteristic that in practically all the cases the condition can be differentiated from other types of esophageal obstruction. But this roentgenological symptom complex applies only to well developed cases. There are, however, types of spastic conditions of the esophagus in which, up to the present time, the roentgenological examination has not furnished as definite diagnostic data as mentioned above.

FIG. 2.—Mrs. J. A. C—. Ulcer of Stomach near Cardia and Cardiospasm.—A. Immediately after ingestion of barium mixture. The latter passed down quite normally. Only slight portions of the contrast mixture are still seen above the cardia. B. 15 minutes after introduction of Delineator. Note fine curving of the string, indicating presence of slight spasticity of esophagus.

In cases of intermittent cardiospasm in which periods of spasticity alternate with periods of normal condition of the organ, the roentgenologist very often presents a negative report, though clinically there may be definite evidence of a pathological condition. This is due to the fact that the roentgen ray examination happened to take place during a free interval in which the esophagus really was in a normal state.

In slightly or even in moderately advanced cases of pure cardiospasm without dilatation of the esophagus, the *x*-ray examination likewise sometimes proves to be negative, as it is difficult to differentiate beginning cardiospasm from the normal slight constriction at the cardiac end of the esophagus. On the other hand, it happens not infrequently that the presence of cardiospasm is being reported roentgenologically in normal cases in which the normal constriction above mentioned is mistaken for spasticity, especially if a thick contrast mixture only is used whereby a stagnation of the ingesta above the cardiac opening is produced artificially and partial obstruction simulated.

This gap in the roentgen-ray diagnosis of spastic conditions of the esophagus is being filled, we believe, by the use of the delineator.

While the examination of the esophagus by means of an opaque mixture gives information in regard to the tonicity of the esophagus wall only during the time of the swallowing process, as watched by means of the fluoroscope—which means during a few minutes at most—the delineator string, once

*Read before the American Association for Thoracic Surgery, June 9, 1919, at Atlantic City, N. J.

swallowed by the patient, may remain in situ for any length of time, outlining permanently the course of the esophagus and reacting even to slight spastic conditions of the organ. In the normal esophagus the course of the string shows a straight line.

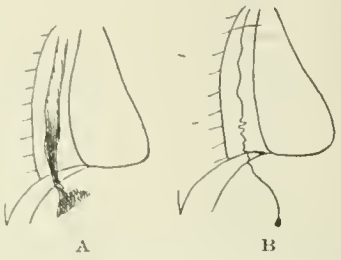

FIG. 3.—Mrs. Arthur R—. Idiopathic Dilatation of Esophagus with Esophago- and Cardiospasm.—A. 2 minutes after barium mixture. Quite marked constriction along cardiac portion of esophagus with moderate dilatation of the latter. B. 20 minutes after introduction of Delineator. Note wave like curves of string throughout upper part of esophagus and marked tortuosity at the cardiac end.

In the spastic organ the course of the string is more or less tortuous, according to the degree of spasticity. The instrument casts a definite shadow on the fluoroscopic screen as well as on the plate. The patient, therefore, can be examined—once the instrument has been applied—repeatedly during any period of time, and at the roentgenologist's leisure, without subjecting the patient to the inconvenience of repeated ingestions of contrast mixtures. If necessary, plates can be taken for records.

The technique, as gradually worked out by us is simple, and can be easily carried out in any desired case. The procedure is as follows: The patient is given the delineator either in the fasting condition or after a light breakfast. The introduction of the instrument is done in the following manner: About 60 cm. of the delineator are detached from the reel on which the string is wound up, the base of the patient's tongue is pressed down with the left index finger, and the ball of the instrument is put deep into the pharynx with the right hand. Immediately thereafter the patient is given water to drink, and the instrument thus slips into the esophagus and later further down into the stomach. Right

Carcinoma of lower half of esophagus and upper part of stomach. 5 minutes after ingestion of barium mixture. B. 15 minutes after introduction of Delineator. Note tortuous course of string along lower half of esophagus.

after the swallowing of the delineator the patient is put under the fluoroscope, and the gradual journey of the string downward is watched. The string hanging outside of the mouth and the reel holding the undetached part of the delineator are arranged so that they do not interfere with the fluoroscopic picture.

By means of the fluoroscope one determines the oblique diameter in which the instrument is seen best. No definite rule can be laid down in regard

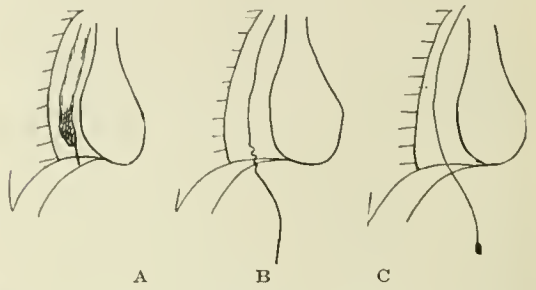

FIG. 5.—Hyman C—. Dilatation of Esophagus and Cardiospasm.—A. During spastic state: 5 minutes after ingestion of barium mixture. Very marked constriction at cardia with moderate dilatation of the esophagus. B. During spastic state: 20 minutes after introduction of Delineator. Note serrated appearance of string at cardia. C. During nonspastic state: 45 minutes after introduction of instrument. Perfectly normal course of string.

to that. Usually, however, the delineator is demonstrated most distinctly in the left or right anterior oblique diameter. But sometimes neither one of these positions gives a good view of the string, and then the patient is turned around until the best possible visualization of the instrument is obtained. The position of the patient is then noted, and plates, if desired, are taken in this diameter.

In normal patients, as mentioned above, the ball of the instrument travels quite rapidly through the esophagus, forming a straight line all along its course. In cases of diffuse esophagospasm the ball is apt to be arrested in its progress downward at any level of the organ, and the string above it appears in semicircular curves. Repeated taking of small amounts of water usually overcomes the spasticity to such a degree as to allow the ball to slip into the stomach; the course of the string, however, is a more or less tortuous one, according to the amount of spasticity present. The accompanying drawings represent exact sketches of the *x*-ray findings of the different cases examined.

In cases of cardiospasm, if the condition is marked

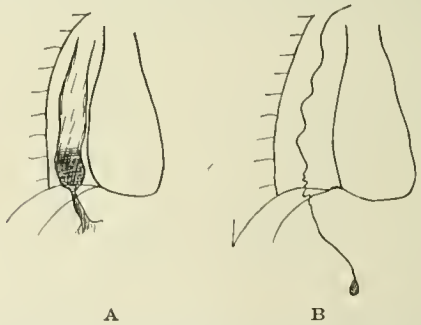

FIG. 6.—Otto P—. Cardiospasm.—A. 8 minutes after ingestion of barium mixture. Almost complete constriction of cardiac end of esophagus with only slight dilatation of the esophagus. B. 20 minutes after introduction of the Delineator. Note tortuous course of string at cardia and slight curving above.

enough, the ball of the instrument is arrested just above the cardia for a longer or shorter period of time, in one of our cases for over half an hour. The course of the delineator in this kind of cases forms a straight line throughout the upper two-

thirds of the esophagus. Throughout the lower third the characteristic zigzag course is noticed, varying in degree from the slightest wave formation to the most extreme tortuosity.

In intermittent cardiospasm, if the examination is

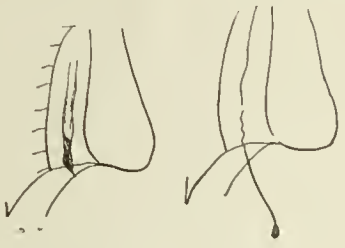

Fig. 7.—Mrs. Leopoldine G—. Idiopathic Dilatation of Esophagus with Cardiospasm.—A. 7 minutes after ingestion of barium mixture. Note very marked dilatation of esophagus above the cardiac constriction. B. 42 minutes after introduction of Delineator. Note wide wave-like curves of the string along the upper part of the esophagus, and serrated appearance of the instrument at the cardia.

done during a state of spasticity, the results are the same as those in permanent cardiospasm. The patient is fluoroscoped repeatedly, with the delineator *in situ*, and it is then noted that during the free period the course of the string, tortuous before, straightens out and remains so until the next spastic attack comes on. When, now, the patient swallows another piece of the delineator, the course of the instrument becomes tortuous again. In one of our cases we were fortunate enough to observe such an entire cycle.

In cases where examination by both the barium meal and the delineator methods is desired it is advisable to do the latter first, as otherwise the outline of the string is sometimes markedly obscured by the previously ingested contrast meal, small portions of which remain sticking to the esophagus wall for a considerable length of time. As soon as the roentgen examination with the delineator has been completed the instrument is gently withdrawn. The delineator is then thoroughly cleaned and sterilized, and is ready for use again.

As we have seen, there is a great variety in regard to the abnormalities of the course of the delineator in spastic conditions of the esophagus. In some cases, wide curves are in evidence; in others, more

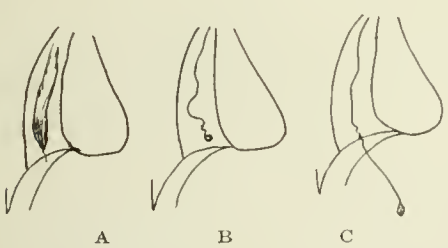

Fig. 8.—Isidore R—. Idiopathic Dilatation of Esophagus with Cardiospasm.—A. 5 minutes after ingestion of barium mixture. Almost complete obstruction at the cardia with marked dilatation of esophagus. B. 25 minutes after introduction of Delineator. Ball of instrument has not passed through the cardia yet. Note curving of string. C. 35 minutes after introduction of Delineator has now passed into the stomach. Note wide curves of string along esophagus and tortuosity at cardiac end.

abrupt tortuosity and even sharply serrated lines. Sometimes more than one type of irregularity is seen in the same case. In cases of very marked dilatation of the lumen of the esophagus above the constricted cardia we see wide curves of the string shadow above the cardia, while at the cardia itself the course of the string shows a more serrated appearance. The former type is due to the fact that the delineator is hanging loosely in the esophagus sac, while the latter is caused by the direct influence of the spasticity of the esophagus wall upon the string.

Conclusions.—The new method of recognizing spastic conditions of the esophagus by means of the delineator appears to be an important addition to our diagnostic instrumentarium. It can be carried out easily in any desired case, and has certain advantages as compared with the older contrast meal method. Earlier stages of spasticity can be recognized by our method, as the string is more sensitive toward tonicity changes of the wall of the esophagus than the barium mixture. The patient can be examined and observed during a much longer period of time, and in this way intermittent spasticity of the organ can be demonstrated in cases in which this condition is liable to be overlooked by the roentgenologist when using the usual method.

MENTAL DISEASES.

By H. LAVESON, M.D.,

NEW YORK.

The pathology of mental disorders may be roughly divided into two parts, the one belonging to the so-called functional maladies, from which recovery is not unusual; the other that of organic degenerative types, in which an eventual restoration to mental health cannot be expected. The boundary line between the two forms is not always sharply drawn, inasmuch as cases which apparently begin as a primary form of insanity may, by repetition or continuance, pass over into the second classification.

Even among the organic degenerative types an absolute pathology—such as is found, for example, in pneumonia, in which definite clinical symptoms accompany certain pathological states existing in the lung—is very rare. It is true that in mental disorders we ofttimes have quite as precise symptoms as those present in more purely physical disease, and one might expect that these clinical pictures would correspond with certain definite changes in the cerebral nerve cell. Such, however, is not the case, except in rare instances.

Of the cell lesions in simple insanities we have but the most vague ideas beyond that during life we are able to note temporary congestions, vascular hyperemias, and conditions suggestive of edema cerebri or the reverse, arterial spasm. With the hyperemias and edemas we know that there can be disturbance of the important outward flow of the lymph from the intrinsic cerebral tissues, and retention of products of tissue waste which can seriously interfere with the proper working of the nerve cell.

In the grosser forms of degeneracy, in the idiot and in the imbecile, macroscopically, deviations from the normal in the development of the brain, the convolutions, cells, or association fiber bands, defects in the architecture of the tissues or of the bony envelope—in a word, malformations of the most diverse kinds—show the retrogressive type of brain and account fully for the deviation from the physiological in the mental functions.

But despite the fact that in the consideration of the pathological substratum of insanity many points are still obscure, there are not a few signposts that point out the lanes and byways by which one may reach something approaching a highroad to the goal. For example, in the various dementias, notably in the so-called paralytic form, in the states of exaltation and depression from gross lesion of the cerebrum and in toxic insanities, a fair conception of some of the processes inducing mental disease is to be ascertained.

Classification.—An accurate classification of diseases affecting the mind is difficult. Various alienists have produced different tables, but I consider the following a very convenient classification:

1. Manic depressive insanity.
2. Dementia præcox.
3. Paranoia.
4. Senile dementia.
5. General paralysis.
6. Syphilitic insanity.
7. Infection and intoxication psychoses.
8. Idiocy and imbecility.
9. Borderland cases: (*a*) neurasthenia; (*b*) hysteria; (*c*) psychasthenia; (*d*) cyclothymia.

Etiology.—1. Civilization: Although insanity is by no means unknown among savage races, there can be no reasonable doubt that it is much more frequently developed in civilized communities; also that as the former come under the influence of civilization the percentage of lunacy is increased. This is in consonance with the observation of disease of whatever nature, and is dependent in the case of insanity on the wear and tear of nerve tissue involved in the struggle for existence, the physically depressing effects of pauperism, and on the abuse of alcoholic stimulants; each of which morbid factors is to be considered separately as a proximate cause. In considering the influence of civilization upon the production of insanity regard must be had to the more involved ethical attitude toward disease in general which exists in civilized communities as well as to the more perfect recognition and registration of insanity.

2. Nationality: In the face of the imperfect social statistics afforded by most European and American nations, and in their total absence of inaccessibility among the rest of mankind, it is impossible to advance any trustworthy statement under this head.

3. Occupation: There is nothing to prove that insanity is in any way connected with the prosecution of any trade or profession *per se*. Even if statistics existed showing the proportion of lunatics belonging to different occupations to the 1000 of the population, if it is obvious that no accurate destruction quoad the influence of occupation could be drawn.

4. Education: There is no evidence to show that education has any influence over either the production or the prevention of insanity. The general result of discussions on the above subjects has been the production of a series of arithmetical statements which have either a misleading bearing or no bearing at all on the question. In the study of insanity, statistics are of slight value from the scientific point of view, and are valuable only in its financial aspects.

5. Inheritance: The hereditary transmission of a liability to mental disease must be reckoned as the most important among all predisposing causes of insanity. It is probably well within the mark to say that at least 50 per cent. of the insane have a direct or collateral hereditary tendency toward insanity. The true significance of this factor cannot as yet be explained or described shortly and clearly, but it cannot be too definitely stated that it is not the insanity which is inherited, but only a predisposition to the manifestation of mental symptoms in the presence of a sufficient exciting cause. The most widely and generally accepted view of the exciting cause of insanity is that the predisposed brain readily breaks down under mental stress or bodily privations. Very frequently we find in the history of insane patients that although there may be no insanity in the family there are undoubted indications of nervous alongside of physical instability, the parental nervous defects taking the form of extreme nervousness, vagabondage, epilepsy, want of mental balance, inequality in mental development or endowment, extreme mental brilliancy in one direction associated with marked deficiency in others, the physical defects showing themselves in the form of insanity.

6. Consanguinity: It has been strongly asserted that consanguinity in the parents is a prolific source of nervous instability. There is considerable diversity of opinion on this subject. The general outcome of the investigations of many careful inquirers appears to be that the offspring of healthy cousins of a healthy stock is not more liable to nervous disease than that of unrelated parents, but that evil consequences follow where there is a strong tendency in the family to degeneration, not only in the direction of the original diathesis but also toward instability of the nervous system. The objection to the marriage of blood relations does not arise from the bare fact of their relationship, but has its ground in the fear of their having a vicious variation of constitution which in their children is prone to become intensified. There is sufficient evidence adducible to prove that close breeding is productive of degeneration; and when the multiform functions of the nervous system are taken into account it may almost be assumed not only that it suffers concomitantly with other organs, but that it may also be the first to suffer independently.

7. Parental Weakness: Of the other causes affecting the parents which appear to have an influence in engendering a predisposition to insanity in the offspring, the abuse of alcoholic stimulants and opiates, overexertion of the mental faculties, advanced age, and weak health may be cited. Constitutional tendency to nervous instability once established in a family may make itself felt in various directions—epilepsy, hysteria, hypochondriasis, certain forms of paralysis, insanity, eccentricity. It is asserted that exceptional genius in an individual member is a phenomenal indication.

8. Periodic influence: The evolutional periods of puberty, adolescence, uterogestation, the climacteric period, and old age, exercise an effect upon the nervous system. The various and profound modifications of the system which attend the periods of uterogestation, pregnancy, and child-bearing, do not leave the nervous centers unaffected. Most women are liable to slight changes of disposition and tem-

per, morbid longings, strange likes and dislikes, during pregnancy, more especially during the earlier months; but these are universally accepted as accompaniments of the condition not involving any doubts as to sanity. But there are various factors at work in the system during pregnancy which have grave influence on the nervous system, more especially in those hereditarily predisposed, and in those gravid for the first time. In the puerperal woman there are to be taken into pathological account, in addition to the dangers of sepsis, the various accidents reducing vitality, the sudden return of ordinary physiological conditions, the rapid call for a new focus of nutrition—are all physical influences which are liable to affect the brain.

9. Toxic agents: The toxic substances which are generally believed to be associated with the causation of mental disorders may be divided into three great classes:

(*a*) Those which arise from the morbific products of metabolism within the body itself—autointoxicants; (*b*) those due to the invasion of the blood or tissues by microorganisms; (*c*) organic or inorganic poisons introduced into the system voluntarily or accidentally.

(*a*) Autointoxication may be due to defective metabolism or to physiological instability, or to both combined. The results of defective metabolism are most clearly manifested in the mental symptoms which not infrequently accompany such diseases as gout, diabetes or obesity, all of which depend primarily upon a deficient chemical elaboration of the products of metabolism. The association of gout and rheumatism with nervous and mental diseases is historical, and the gravest forms of spinal and cerebral degeneration have been found in association with diabetes.

(*b*) The results of modern research point to the growing belief that microorganisms of the infectious diseases, such as influenza and typhoid fever, have a noxious influence on the nervous system.

(*c*) Accidental or voluntary poisonings of the system which result in insanity are illustrated by the forms of insanity which follow phosphorus or lead poisoning, or pellagra; the voluntary intoxication of the system by such drugs as morphine and alcohol.

Hallucinations and Delusions.—Hallucinations are those vivid inner thoughts of the mind which appeal to the patient just as strongly as if they had originated in external sensory impressions. Delusions result from erroneous reasoning and faulty conclusion. Hallucinations and illusions are errors of the mind by which in the one case ideas are taken for matters of fact, and in the other case real objects are falsely represented. In this state the mind is supposed to transfer the products of creations of its fantasy to real life and to persuade itself that it has heard, seen, or felt, as in the normal condition, when it has really only imagined it heard, saw, and felt. Thus in paranoia hallucinatoria generally the sufferer hears taunting or insulting voices calling after him in the street and making injurious insinuations about him, or sometimes unseen speakers incidentally let fall words which confirm his forebodings. Many sufferers see the persecutors who torment them from a distance by means of magnetic and electrical apparatus. They entertain kings and princesses and receive angels' visits; all these hallucinations occur in a state of full consciousness. In some cases they are highly varied and in others they are characterized by extreme monotony, and in others they are closely bound up with the dominant fixed idea which they illustrate. Where hallucinations of taste have been noted they are mostly nauseous or poisoning, and frequently give rise to refusal of nourishment, or it may be to continued spitting. Olfactory hallucinations are, on the whole, infrequent, and are seldom of an agreeable character. The experiences of the patient who declared he smelt all the perfumes of Arabia and the East are exceptional, for hallucinations of this sense are, generally speaking, associated with delusions about bodily foulness and odors of corruption and corpses, due to visceral disturbances. Hallucinations are a frequent cause of violent and criminal acts; for instance, in hallucinatory insanity, epilepsy, hysteria, and somnambulism, and especialily in delirious states. Thrown into a paroxysm of terror by the phantoms which threaten him, or obsessed by his "voices," the sufferer snatches up a weapon and perhaps commits a murder or sets fire to the house. Or, again, despairing of escape from the enemies who pursue and mock him, he puts an end to his sufferings and his life at the same time, and often in a skillful and cunningly planned manner. The commonest visual hallucinations are black rats, cats, snakes, and spiders, shining stars, fiery spheres, and so on.

Hallucinations are a constant phenomenon of ecstasy, where they arise out of one-sided mental activity and intense concentration on a single group of ideas, conjoined with lowered sensibility. The best-known cases are those of religious ecstasy. Owing to the persistent euphoria associated with this state, and the ease with which the psychical processes act, ecstatic visions and hallucinations are almost invariably of an agreeable nature. The subjects of these experiences mourn the short duration of their happiness, and tell with rapture of the heavenly bliss and unspeakable delight which they enjoy, of the wondrous visions vouchsafed to them, and the converse they have held with angelic visitors. Sometimes, indeed, they speak of awful phantoms. The many familiar examples of ecstatic visions in the Old and New Testaments may be cited, as well as those found in the legends of the saints and martyrs, where they either appear as revelations from heaven or temptations of the devil. The hallucinations associated with intoxication are generally of a depressing nature, and terrifying impressions predominate. They have visions of serpents, vermin, reptiles, rats, cats, snakes, mice, and monkeys.

CYCLOTHYMIA.

Under this form we include the mild forms of manic-depressive psychoses and the manic-depressive constitution.

One does not often enough appreciate, and certainly one cannot too often repeat that one frequently observes, both in the family circle and at large, individuals who are not considered as sick, even less as mentally affected, and whose entire lives are passed isolated for the most part by the people who surround them, in a successive round of periods of moderate excitement and of slightly pro-

nounced melancholy, and who are in reality afflicted in an evident degree, but more attenuated, with this form of mental malady. They continue to live the life of the community, or the family life, without any necessity of treating them as sick, even quite far from considering them as having a psychosis, and, above all, of shutting them up in asylums. So much so, that when in a period of excitement these individuals simply appear to have changed their character and to have momentarily acquired 'an unaccustomed activity.' They occupy themselves with business, they make numerous visits, they write letters to those that they are not in the habit of visiting frequently; they have a desire to be incessantly on the move; they sleep very little, make numerous trips or projects. They take up with feverish activity the duties of their profession, or even take up new business schemes, which they seek to advance to a state comparable with their habitual occupations. They show, on all occasions an exaggerated gaiety. They show themselves to be intelligent, loquacious, and even spiritual, and although there may be always present great disorder in their acts, and a certain disconnectedness in their speech, those who have not known them for some time, or those who have not observed them at other times, are unable to judge of their true mental situation, although the diseased nature of this state does not escape an attentive observer, and is often appreciated with exactness by the members of their families or by those who live with them habitually.

The diseased character then manifests itself otherwise when, after a more or less prolonged period of excitation, which has passed for a simple change of character, there supervenes little by little, or all at once, in those individuals who up to then had shown gaiety and an exaggerated activity, a state precisely the reverse to such a degree that one would believe they had to do with two different individuals. Instead of showing this exuberant activity which ceases to feel either fatigue or the need for rest, these patients cease to go out, to make calls, to do business. They change their character completely; they become sedentary, incommunicative, almost mute; they flee from the world, seek solitude and isolation; speak little, or reply briefly to questions addressed to them; complain of general malaise, of a very sad state of suffering, of precordial anxiety, of loss of appetite; they are sad, unhappy, anxious without reason. They are conscious of their own condition and regret it, but cannot be brought to modify it; they thus come to acquire a distaste for living, to refuse food, and in extreme cases they shut themselves up in their rooms for several months without attracting in a notable manner the attention of those about them, especially when one knows that they are the subject of what are vulgarly called "the blues."

As for the public, they see these people from time to time, and think of them as eccentric characters, gay and lively, and of feverish activity, such as they have observed with certain individuals, but they do not suspect the existence of a morbid state, which is appreciable only by the successive reproduction of periods of excitation and of depression which the world is not called upon to determine. The feature which should characterize cyclothymia from others of the periodic psychoses is solely an attenuation of a dysthemia and hyperthemia indicating variations in the emotional tones of the patient with intact intellectual faculties. The chief and fundamental symptom of the depressive stage of cyclothymia is the psychical retardation with absence of all delusions and hallucinations associated with an intense and definite even though not always correct insight. They have the feeling that they will never be able to do any more work, and that they do everything upside down; of their indifference to persons and things which had been of great interest to them. They must be pushed to accomplish anything; prefer to be left alone, and reject the overtures of friends because it may be necessary to talk to them. One symptom in particular is noticeable by reason of its contrast with the patient's complaints of apathy and indifference. This is a very striking tendency to and capacity for criticism. The whole condition is often likened by the patient to a machine whose oil is dried up, while in the contrasting state the patients speak of the machine as too well lubricated.

Another mild form of manic depressive phychosis is what Kraepelin terms "hypomania," or "mania mitis." In this form the patients feel themselves the sense of well-being, they are wittier, cleverer, and more capable than on healthy days. The tendency to fault finding which, as has been seen, is present in the depressed phase, is strikingly amplified or modified. These patients often have a very scornful, mocking attitude, and the internal unrest leads to more or less exaggerated activity. Not only can these patients stand more continuous work than on their well days, but not infrequently is the character of the work a great deal better. Life is seen now only on its rosy side. The desire to help everybody, and interest themselves in everything, is manifest throughout. Much philanthropic overactivity and many reform propaganda receive their greatest stimuli from minds in this hypomanic stage. Hecker relates an instance of multiple marriage engagements made in the euphoric state and broken in the depressive phase of this disease.

MANIC DEPRESSIVE INSANITY.

During the state of depression there is evidence of want of vigor in all the bodily processes. The mouth is dry, the digestion is sluggish, the bowels are constipated, the pulse is feeble, the breathing is shallow, the muscles are flabby, the bodily activity is diminished. Together with these bodily manifestations goes a depression of spirits which varies in degree from a trifling want of buoyancy to the profoundest misery and despair. In mild cases the melancholy amounts only to a feeling of dissatisfaction, of diffidence in their own powers, and general vague unhappiness, but in severe cases the depression is so great as to lead to attempts at suicide. The patient has a most miserable expression of the face, his head droops on his breast, his arms hang listless by his sides, his forehead is puckered into innumerable wrinkles, his eyes are sunken, his mouth is a picture of woe, and his whole attitude and expression are suggestive of misery and despair. He complains that he is the most wicked of men, that he is accursed of God and man, that he has committed the unpardonable sin, the sin against the Holy Ghost, that his wickedness is unspeakable,

that he is unfit to live. In some cases there is simple depression, a feeling of unhappiness, which is not justified by the circumstances of the individual and for which he is unable to account. But when the disorder of feeling is profound it is always accompanied by more or less disorder of intellect, by more or less marked delusions. If a patient has but a slight degree of melancholy he has a delusion that he suffers from some comparatively slight misfortune, as, for instance, that he is afflicted with the itch, or that he has a weasel inside him. If his depression be of a more severe character his delusion is that he is suffering from a greater misfortune, as that he has lost his fortune and is coming to the workhouse.

If he is buried in profound gloom, his delusion is that he is the unpardonable sinner, that he has forfeited the mercy of God, and will suffer eternally in hell. The melancholic person invariably exhibits an undue lack of bodily activity.

In the exaltation there is exaggerated activity in the conduct, his conversational powers are exalted. There is a general sense of well-being, the hesitating man becomes fluent, the dull man bright, the slow man quick, the serious man sees a joke with an unwonted readiness of appreciation. His hours of sleep are abbreviated and his waking hours longer, though they are more fully employed, are more crowded with activity than ever before. His bearing and demeanor are eager and restless. He is constantly in motion, and his talk is rapid and hurried. He meddles with everything that he comes across; he writes dozens of unnecessary letters; he talks with undue vehemence, rapidity, and at undue length.

Delusions of grandeur occur most commonly in association with heightened nervous tension and increased feeling of well-being. Thus a patient with a glorious exaltation, of a most jovial and smiling aspect, and of eager and incessant activity, claims to be the Almighty Himself.

Treatment.—During the stage of melancholy we must endeavor to procure sleep, to accelerate and revivify the process of nutrition and to raise the tension of the nervous energy. The measures that should be taken to procure sleep are too long to set forth here in full. This much may be said: No attempt should be made to procure sleep by means of drugs, certainly not until all other means have failed. Sleep so procured has never the efficacy of sleep that is brought about by more natural methods; usually, large and even dangerous doses of soporific drugs have to be given before sleep can be procured, and it not infrequently happens that by no amount of the drug that can be given will sleep be obtained. I have seen more than one patient the sufferer from persistent, obstinate insomnia, dosed with chloral and bromide of potassium, without ever going to sleep.

We must take measures to promote the activity of nutrition. If the patient refuses food, with suicidal intent, we must compel him to take food. Of all the tasks of the alienist physician, none is more difficult; of all the heavy responsibilities, none is more onerous, than that of determining when the tendency to suicide in any individual case has so far subsided as to allow of the patient being restored to home, to friends, to society, and to liberty. A patient is admitted to an asylum in deep melancholia; he improves in health, he becomes cheerful, he becomes active, his delusions subside, he says that he feels better, that his former fancies have departed, that he recognizes their falsity. He is watched for days and weeks, and as his improvement is maintained, and he seems quite recovered, he is allowed to go home. Next morning he is found hanging from a gas bracket.

DEMENTIA PRÆCOX.

The triple clinical division suggested by Kraepelin —namely, the hebephrenic, catatonic, and paranoid forms of the disease—is fairly satisfactory if the attempt at differentiation is not pushed to the extreme. Little is to be gained by the efforts sometimes made to distinguish too sharply between these groups, as many of the symptoms are common to all three forms.

The periods of puberty and adolescence are unquestionably the times at which the majority of the cases develop. The onset of the disease is frequently insidious owing to the so commonly slow progression in the earlier stages of its development, no less than to the protean character of the symptoms. There is no other form of alienation in which an intimate knowledge of the individual is of greater importance as an aid in establishing the diagnosis at an early period of the disease than in dementia præcox.

Mode of Onset.—If a careful history is obtained, it is generally possible to show that the patient for years prior to the onset of the more definite symptoms of alienation, have exhibited eccentricities of character. They are said by their parents to be seclusive, to shun other children, to be jealous, overparticular in matters of dress, and generally hypercritical. Up to a certain period, generally about the time of puberty, these patients may develop rapidly intellectually, but show marked capriciousness and general emotional instability. At times they are given to brooding long upon subjects which generally do not interest children of their age. When the period of puberty approaches, these individual idiosyncrasies become more marked, the patients grow more seclusive, more irritable, and markedly emotional. It is noted by their friends that they rapidly become singularly unconventional, and are looked upon as "queer fish." The memory may or may not be greatly impaired. Vague suspiciousness develops. The patient becomes self-centered, gives expression to indefinite fears, is distrustful of the members of his immediate family. Some patients rarely take the initiative in conversation, while in others there may be a typical disorganized ataxic expression of ideas with considerable speech compulsion, differing essentially, however, from that seen in maniacal states. The complaints made by the patients are frequently numerous and varied. They affirm that something is queer in their heads, deplore their state of mental depression, complain of insomnia, of disturbances in the various organic sensations. In milder cases the hallucinations and delusions are lacking in vividness and sensory plainness. They are sometimes referred to as simple light or color sensations, or indefinite sounds. At other times the patients affirm that they see grotesque and bizarre figures or hear voices. In a

comparatively large number of cases these disturbances of sensation seldom reach any degree of severity. There is marked disturbance in the volitional acts. The patients lounge about the wards. The facial expression is apathetic. They sit motionless for hours, taking little interest in their surroundings. The orientation in the milder cases is fairly well preserved. Not infrequently, in testing the memory, it is observed that many patients give correct answers to a number of questions and then suddenly the replies become irrelevant, farcical, and puerile. The patients remember coming to a hospital, give the year correctly, the day of the week and month, and then fail utterly to recall their own names. As the dementia advances many of these patients exhibit occasional signs of negativism, stereotypy, and automatism, but there are cases in which these symptoms are more or less marked from the beginning to the end of the disease.

The absence of a well-defined motive, the disorganization of connected thinking, and the anomalous emotional state, are the factors that are responsible for the actions of the patient. In nearly all cases there is a general blunting of the emotional tone. This is very characteristic. The patients become very indifferent to their most intimate friends as well as to members of their family. Not only is there marked impairment of the patient's sympathies and affections, but at times a paradoxical reaction in the objective expression of the feeling tone occurs.

PARANOIA.

By paranoia is understood a psychical disease essentially chronic and progressive in nature, and characterized by systematized delusions of persecution.

The recognition of the disease derives its great importance in psychiatry and medical jurisprudence, not from its frequency, because it is relatively one of the rarest forms of mental disturbance, but from the fact that oftentimes the affected person is a highly dangerous individual, frequently able to conceal his insane concepts not only from the laity but also from medical men until an outbreak of a violent character has taken place, which is not unlikely to result in death or injury to others. The person seldom believes that the outer world has altered its relations to him; everything is seen in an unfavorable light; a spell, which he has no will or energy to remove, is upon him; everything is a burden. Friends no longer treat him as of old; they slander him behind his back. Persons speaking together on the street regard him with an unfriendly eye.

Self-correction is at first attempted, but the old reticence of youth prevents him from inquiring into the significance of these changes in the disposition of society toward him, and his own irrational reasoning as to the meaning of the change strengthens his misconceptions. Soon relatives and friends are converted into deadly foes. He is hounded on the street, slandered by the passer-by, his family distrust and annoy him, they place compromising papers, mysteriously worded, among his effects. The newspapers are full of his misdoings, the preachers talk at him in their sermons, holding him up as an example of sin and immorality, and making him a scapegoat for the misdeeds of all mankind. Closer and closer the net of the systematized persecution is drawn around him. Astounded, he retires more and more within himself; if spoken to, he is irritated; if left alone to follow his own devices, he regards it as a studied insult. The evolution of this persecutory system lasts over a number of years before the limits of the borderland of insanity are passed. Gradually, or suddenly, as the case may be, there comes an hour when, after exhausting watching or some exciting scene produced by his falsified impressions, certainty is reached that attempts are being made to poison him, to rob him of his possessions, or to take away his life by hypnotic influences.

Very different from the extravagant and ridiculous ideas of the paranoid type of dementia præcox, and even more so from the delusions of melancholy, progressive paralysis which are unstable and disconnected, the delusion of genuine paranoiacs is plausible, unyielding, and nourished by a perverted but robust and irreversible logic. Paranoiacs conduct themselves as to persons of sound mind, and except in the matter of their delusion, reason with good sense. Their power of reflection, self-esteem, and dignity are never diminished; there is never occasion to record in them either a morbid tempest of passion, an eclipse of consciousness, or a general upheaval of their whole being. The paranoical delusion is, therefore, not the common expression of a morbid disturbance, but is the product of a monstrosity of the intellect which exists first in germ, and inevitably matures in full vigor of health and age; it does not arise by revolution but by evolution; it is not a disease but an anomaly; or, more correctly, the indicator of an anomaly. Owing to their lucidity of intellect and coherence of conduct, paranoiacs form the aristocracy of asylums; indeed, the majority of them have little difficulty in avoiding confinement in them.

Treatment.—It consists in the necessity of having recourse to the asylum in order to protect his family from the consequences of his folly, and thus paranoiacs become the ornament and distinction of that part of the asylum which is reserved for the best conducted, most composed, and most lucid of its patients. The attempt may be made to convert by frank but considerate argument. A successful result will, however, be obtained only by the man who can wait patiently, and who can act humbly when opposed by the haughtiness of the paranoiac.

(To be concluded.)

CLINICAL RESULTS WITH A METHOD OF TESTING THYROID FUNCTION.

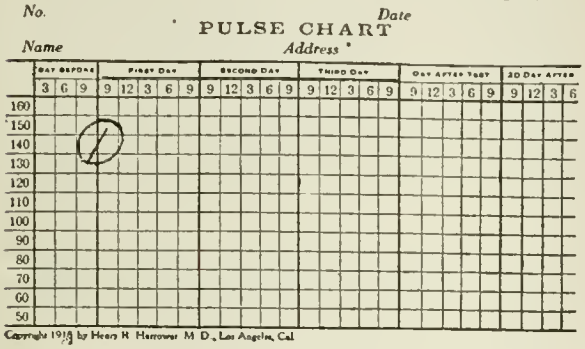
By HENRY R. HARROWER, M.D., F.R.S.M. (London),

GLENDALE, CALIFORNIA.

MANY times the reaction of an individual to organotherapy serves as a fairly good index to the condition of the endocrine glands which correspond to the gland from which the extract was made. That is to say, individuals with a sensitiveness in a given gland are likely to react more quickly to organotherapy than those in whom there is an apathy. This is more particularly true of the thyroid, and many hundreds of physicians have given thyroid extract to patients and in a short time had to dis-

continue it because it made them nervous and irritable, unduly stimulated the heart and evidently was not accomplishing what was desired.

Based upon a number of clinical experiences of this character, I have devised a very simple, but



none the less useful, method of testing thyroid function, which was announced originally in the MEDICAL RECORD, August 3, 1918. The test consists of giving definite and increasing doses of thyroid extract, with a suitable inert excipient, in a uniform and routine manner, while a careful and regular study is made of the pulse and other symptoms which may ensue. The information obtainable in this manner is of much service, for it amounts virtually to a differential diagnostic measure in the study of goiter.

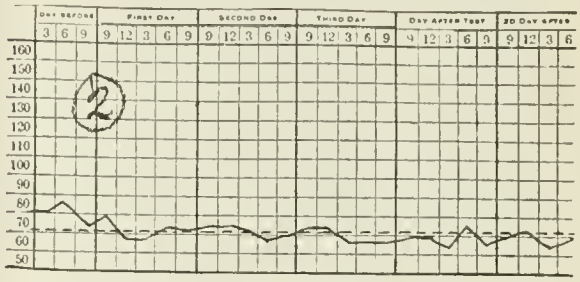
It will be recalled that from the secretory standpoint there are two distinct varieties of goiter; (1) the simple enlargement of the gland, which appears to be an effort on the part of the organism either to supply an increased demand for its particular product which may be deficient, or to produce a greater supply than usual because of an increased demand for it; and (2) the hypertrophy, which is due to some extraglandular cause, such as toxemia or any form of irritation. The former, or simple goiters, are a useful attempt on the part of the body to render the best service possible under the circumstances and usually are benefited by a course of treatment which includes the administration of thyroid, iodine, etc., which thus tends to supply the need, in part at least, and render the friendly encouragement of the gland unnecessary.

In the other class of cases, however, the conditions are decidedly different, for the thyroid gland is being overworked and driven faster than normal. This is usually brought about by the toxins absorbed from foci of infection, from emotional disturbances or from deranged functions of some of the other endocrine glands. In such cases, the thyroid gland is more sensitive and hence more unruly; and just as the hypertrophy differs very materially in origin, so it differs in its responsiveness to treatment. In fact, what would be most beneficial in simple goiter would be most detrimental in the goiter due to hyperthyroidism, and the administration of my "Thyroid Function Test" enables one to differentiate the early functional stages of thyroid sensitiveness, *i.e.* between latent hypo- and hyperthyroidism, and accomplish something worth while in the treatment.

The materials for the thyroid function test consist of four doses each of ½, 1 and 2 grains of thyroid in graduated capsules together with a chart similar to the one illustrated (Fig. 1), to which is attached printed instructions as follows:

Each package of "Thyroid Testing Capsules" contains twelve capsules of three graduated strengths and sizes. A pulse chart accompanies each, with explicit instructions as to how to fill out the record.

After the consultation, at which the first pulse-counting is done and recorded, the patient counts the pulse



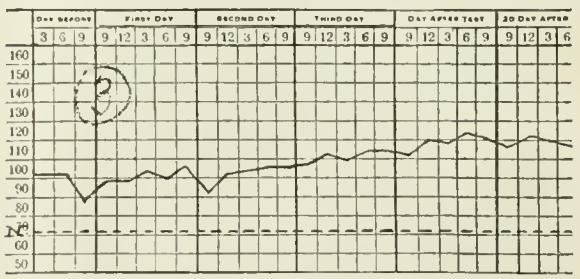
again at 6 and 9 o'clock; and the following morning commences to take the four small capsules at 8, 10, 12, and 2 o'clock, with a swallow of water, recording the pulse five times a day—at 9, 12, 3, 6, and 9 o'clock. On the second day the four medium-sized capsules are taken at similar hours, and the pulse is again recorded under as nearly identical conditions as possible and at the same hours.

During the third day the four large capsules are taken at the same hours as previously and the pulse is again recorded as before. The fourth day, or the "first day after" finishing the ingestion of the capsules, the pulse is recorded as before, and again during the forenoon of the fifth day, when the chart is completed (and plotted, if convenient), the physician is consulted, and the data thus secured carefully studied.

It is important to watch for symptoms such as irritability (temperamental or nervous), twitchings (of the eyelids, lips, fingers, etc.), breathlessness, and other nervous manifestations. If it should happen that on the second or third days these symptoms are present and prominent, the remaining capsules should not be taken; but the chart is completed, while on its reverse side a brief statement is made of the symptoms, giving the time of onset and other related facts.

NOTE.—Take the pulse under as nearly uniform conditions as possible, preferably before eating, after a ten-minute rest and sitting. Mark the chart in the proper square with a dot at approximately its relative position, *e.g.* 72 would be just above the 70 line, 86 would be about the middle of the space between the 80 and 90 lines, etc. Be regular and persistent. The information thus obtained is worth all of your trouble!

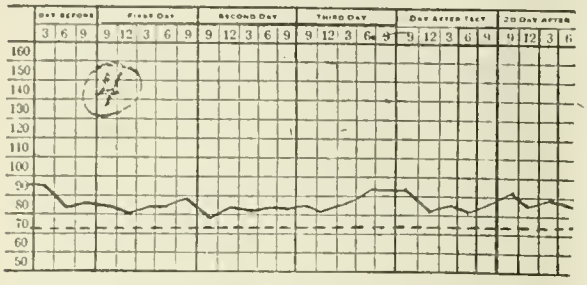
The reaction of the patient to this routine administration of uniform doses of thyroid varies very materially, depending upon the factor that we are attempting to discover. In the apathetic hypothyroid cases, practically no difference in the pulse figure is found, and as in these cases cardiac action, like practically every function of the body, is lazy and slow, the pulse figures are low and remain so.



The reaction to the thyroid testing capsules in a case of functional hypothyroidism which had not yet advanced to a stage where the usual findings of myxedema are noted is nicely illustrated on the accompanying chart (Fig. 2). Here it will be noted

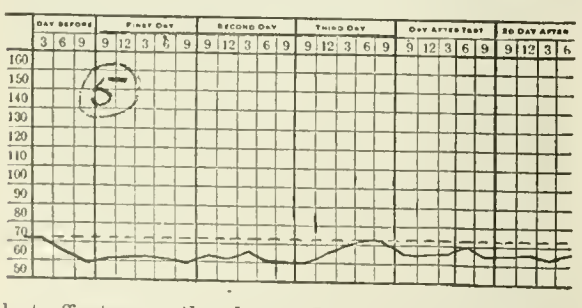
that the pulse is below the normal and does not seem to be influenced whatever, even by the heavy dosage of thyroid which is given on the third day.

In the normal individual, on the other hand, the thyroid feeding is going to temporarily stimulate



the thyroid function, and hence, through it, the heart rate; and it is customary, during the third day of taking the capsules, for there to be an increase in the pulse, which, however, is due to the administered thyroid extract rather than to any excess of the thyroid hormone which may be produced in the body; and since these products are destroyed quite rapidly, the cardiostimulant action merely lasts during the time of the greatest dosage of thyroid and comes down to normal again the day after.

On the other hand, in the various stages of thyroidism, the pulse findings are characteristic: the greater the susceptibility, the wider the range. First of all, as will be noted in the accompanying chart (Fig. 3), the average pulse rate is somewhat higher than normal, and there is also more irregularity than usual. Early in the administration of the thyroid, the pulse begins to be more rapid until, during the height of the temporary gland feeding, it may reach well above any possible normal figure—110, 120 or even higher. Since this stimulus is not entirely due to the product which has been administered but to the increased activity of the supersensitive gland, following the removal of the medication, *i.e.* "the day after" and "the second day after," the pulse still remains up because the thyroid is working overtime, as is indicated very clearly on the chart. In fact, in well defined hyperthyroidism with tachycardia this test should not be used, nor need it be, for the diagnosis should be clear without it, and in latent cases in which there is an unexpected degree of thyroid sensitiveness, it will be noted that the routine advice calls for the omission of the last four capsules—the largest doses—but the continuation of the pulse tracing, with a note to



that effect upon the chart. In such cases, the variations in the pulse findings will not be so exaggerated, merely because the test has not been completed, but the indications are equally obvious and helpful.

This test is more useful in the discovery of thyroid apathy or a latent degree of thyroid sensitiveness than in the diagnosis of frank hyperthyroidism, for reasons which will be clear. Two out of many hundreds of cases that have been treated in this manner showed charts which were quite unexpected and worthy of comment. The first was an individual with a highly nervous attitude, staring eyes, fine tremor, sweating palms and general sympathetic irritation. He was a "typical case of hyperthyroidism," yet some of the findings were missing, especially the fact that the pulse was approximately normal. A thyroid function test was made and the following chart secured (Fig. 4), the later an *x*-ray examination of the chest showed a sub-clavicular tumor of considerable dimensions. The sympathetic irritation was due largely to the pressure of this intrathoracic tumor, and the patient did not have "typical hyperthyroidism" after all.

Another case of an opposite character had a large goiter which was about to be operated upon for cosmetic reasons. The physician about that time happened to hear of this test, tried it and later sent me the accompanying chart (Fig. 5), from which it seemed clear that the patient had a well defined degree of thyroid inactivity, and at my suggestion various other symptoms of Hertoghe's disease—"myxœdème fruste"—were discovered, the patient was given medication calculated to stimulate the thyroid and ovarian functions, and the goiter almost disappeared eventually, and the menstrual difficulties, which were quite prominent, were controlled simultaneously. In this particular case, the thyroid function test saved an operation by giving broader information in regard to the patient.

Still one other class of cases may benefit materially from the use of this test: I refer to the chronic toxic and nutritional disturbances such as rheumatism, neurasthenia, tuberculosis, etc., in which elimination is very much below par and there seems to be a radical reduction in the oxidizing process. In such cases, a thyroid function test may indicate a marked degree of thyroid apathy and direct attention to the possibility of stimulating this deficiency, with decided prospects for benefit from the obviously necessary thyroid therapy. It is perfectly true that many such cases receive benefit from the use of thyroid extract without the test, but there is a much greater satisfaction in having a definite reason for each procedure when this is possible.

My reference to tuberculosis calls for a word of explanation and caution: Many tuberculous persons have a well defined thyroadrenal insufficiency, and the thyroid function test indicates this clearly, so does the blood pressure and the uranalysis. This naturally calls for obvious associated gland support. On the other hand, since the thyroid gland is expected to react to stimuli of a toxic nature, a latent degree of hyperthyroidism may be indeed present and easily discoverable following this test, in which case any glandular treatment which might be in order would be the opposite from that given to the other tuberculous persons in the large class mentioned previously.

It has been said that this thyroid function test is nothing but the administration of thyroid extract and the usual noting of the patient's reaction, but unfortunately most of our experiences of this character have been our failures, and our clearest recol-

lections about them were the remarks made about the uncomfortable feelings which resulted from the administration of the thyroid extract for a week or two, and caused us to stop it at once. Further, the fact that this test is ready to use, that there are printed instructions and a chart available, directs attention to and makes convenient a measure which ordinarily may not be thought of; hence I feel justified in emphasizing the importance of this procedure, nor merely in the differentiation of goiter as indicated, but in the search for scientific reasons for the use of thyroid extract as a part of the treatment in a given case.

THE RESULTS OF NONSPECIFIC VEGETABLE PROTEIN THERAPY IN CASES OF BRONCHIAL ASTHMA.

By ALEXANDER STERLING, M.D.

PHILADELPHIA, PA.

By way of introduction I would define a few terms. It seems that a great number of students and physicians are rather misinformed as to the meaning of foreign protein, protein sensitization tests, and nonspecific vegetable protein therapy.

Protein skin tests or allergic skin reactions, for convenience sake are termed "protein tests"; they are undertaken to determine whether or no a certain individual has an idiosyncrasy in regard to certain food principles, such as meats, rice, milk, casein, etc. Minute quantities of the proteins from these food principles are introduced by the dermic or intradermic method to determine by the occurrence or absence of reaction whether they agree or disagree with the particular individual, or whether they have anything to do from an etiologic point of view in the production of bronchial asthma, chronic skin diseases, or urticaria, angioneurotic edema, etc.

If a patient is found sensitive to a certain protein it may or may not be the only particular responsible factor in the production of the disease in question. One may also desensitize a patient by gradually increasing doses of a weak solution of the particular protein which at first has caused a reaction. (I. C. Walker.)

By the term foreign protein treatment is understood the intravenous injection of typhoid, paratyphoid, or other vaccines, in disease conditions like rheumatism, arthritis deformans, gout, etc.

Nonspecific vegetable protein therapy is understood to be the treatment of a disease such as asthma, anemia, or tuberculosis, with watery extracts of certain seeds or leaves containing 2 per cent. nitrogen protein, given hypodermically.

The last is the one about which I am going to speak in the present paper, giving the results of investigations carried out in the Out-Patient Department of Clinical Medicine in Jefferson Hospital. My thanks for permission to do this are due to Dr. S. Solis Cohen.

The decoctions of certain grasses—*i.e.* the seeds or leaves—are neutralized, put up in ampoules, and sterilized, and so made safe for hypodermic treatment. They were supplied to me by Dr. Henry S. Williams of New York, and were of four different kinds:

No. 39. Proteins of alfalfa seed.
No. 42. Proteins of rape seed.
No. 45. Protein of alfalfa seed, alfalfa meal, and millet seed.
No. 65. Proteins of alfalfa meal, alfalfa seed, mustard seed, rape seed, and millet seed.

I have confined my study of these nonspecific vegetable proteins to their effect on bronchial asthma, the material comprising 19 cases in all. One of the great problems of the practitioner of internal medicine is the bronchial asthma patient. The chronicity of its course, the thousand and one etiologic factors, and consequently the hopelessness of its cure, even in the hands of the expert, make the patient skeptical and cause him to seek relief from many physicians and hospitals. The careful observer will meet a few types of bronchial asthma, as far as the time of the paroxysms and physical findings of the chest are concerned.

Physical Chest Findings.—Type I.—Paroxysmal dyspnea is more or less constant; the chest is never clear from adventitious sounds, and no matter how well or ill the patient may feel, whether he has a paroxysm or not, the chest is full of those so-called wheezing sounds.

Type II.—The dyspnea is present only during the attack; the chest is absolutely clear of adventitious sounds in between the attacks; if one examines the patient when free from an attack, one will pronounce it a normal chest upon physical examination.

Type III.—The patient claims to feel perfectly well in between paroxysms, and looks well, but upon a thorough physical examination in some corner of the chest the presence of adventitious sounds will be found—it may be the right or left upper lobe, the right or lower left lobe, anteriorly or posteriorly; and one is sure to make a diagnosis that the patient suffers from asthma.

Time of Attacks.—Type I.—Nocturnal paroxysmal dyspnea occur from 2 to 4 in the morning, while the rest of the 24 hours a cough is present, with more or less expectoration, but without dyspnea.

Type II.—Paroxysmal dyspnea occurs in from four to twenty or more attacks in the 24 hours, at any time of the day or night, although the night paroxysms are more severe.

Of this series of 19 patients 3 were private patients, 16 were from the Out-Patient Department of Clinical Medicine at Jefferson Hospital. Two patients derived no benefit whatever, as regards either the objective or subjective symptoms. Four patients had slight improvement. Their attacks were not severe, they felt stronger, although there was no marked change upon physical examination. Ten patients showed very marked improvement upon physical examination. They passed many nights and days without having any attacks for the first time in many years, and there was marked general improvement all around, which could not be attributed to anything else than that these injections produced the reduction in the frequency and severity of their paroxysms. They were so mild that the patients expressed themselves as perfectly content if they could remain in that condition permanently. Three patients improved immediately, and felt as

*Study No. 2; see article by the author in the *Pennsylvania Medical Journal*, December, 1918.

though they had never had any asthma at all, and that condition had continued when I saw them two months ago. These 19 patients were not given any other medication whatever so that we might be in a position to see what these injections of vegetable extract will do. The only other medication given was morphine gr. ¼, atropin gr. 1/100, hypodermically during an acute attack to two patients. In not a single instance did I find that these vegetable proteins had any abortive influence on the paroxysm.

To this series of patients were administered the protein of vegetable extracts Nos. 65, 39, 42 and 45, as follows: No. 39, five drops at the beginning, increased daily by 2 drops, up to 1 c.c., which was then continued for one week. No. 42, 1 c.c. every other day for one week. No. 45, 1 c.c. every other day for one week. No. 65, 1 c.c. every third day for two or more weeks until the patient had had from 20 to 25 injections. If there was no improvement at the end of that period no further treatment with the vegetable proteins was attempted.

Case I.—Mrs. H. R., private case, 29 years old, has two children, cough for 9 years, asthma 7 years. Urine shows slight trace of albumin. Temperature 99°-99.5°, pulse 90-100; sputum on repeated examination negative to tubercle bacilli. Blood count: whites, 7,500; reds, 6,500,000. The attacks are both nocturnal and diurnal, from 12 P. M. to 3 A. M.; 8 to 10 A. M., and 4 to 8 P. M. She had never passed a week, not even a day, free from attacks for seven years. Physical examination of the chest shows type II. After one week of injections she passed one night for 13 hours free from paroxysms. After two weeks of treatment she had but two or three mild attacks in the 24 hours. Result: patient much improved.

Case II.—Mrs. F. D., 48 years old, has four children. Has had asthma for fifteen years; attacks day and night, worse at night; temperature 98°, pulse 80-90. Urine shows slight trace of albumin, otherwise negative. Blood count: whites, 8,200; reds, 5,420,000; blood pressure, systolic 100, diastolic 80. Physical examination of the chest shows type 1. After two weeks' treatment the patient could sleep every night from 11 P.M. to 5 A.M. without any paroxysms, which she had not done for 10 years. The patient had fifteen injections. Marked improvement.

Some of the improvement in the severity and frequency of the paroxysm might be ascribed to the psychic effect, the patients deriving a certain amount of satisfaction from the general care and attention. But the psychic effect is not lasting, and would not influence the result of the urine examination or of the blood count.

When one can realize objective and subjective improvement in the patient, then, and only then, can a certain therapeutic measure be asserted to be of value.

The cases selected for this series from the O. P. D. of Jefferson Hospital were bronchial asthma only, excluding cardiac, renal, and other forms of dyspnea. Two of the 19 cases had emphysema and seven had chronic bronchitis.; two of those that had bronchitis also had bilateral pleurisy.

Case III. (No. 5467).—F. W., 15 years old, asthma for 11 years, March, 1918; paroxysm nocturnal type. Examination of the chest shows type III; pulse 90-100, temperature 99°-99.5°; urine examination negative; sputum examination repeatedly negative to tubercle bacilli; blood pressure, systolic 100, diastolic 80. The x-ray gave no evidence of substernal thyroid. Left hilus shows a matting together of the glands with a change in the normal shadow which is suggestive of acute tuberculosis in the upper part of both lobes. Skin reactions negative to all protein tests. (For the number and kinds of tests, see the author's article in the *Pennsylvania Medical Journal*, December, 1918.) The patient received 20 injections. The paroxysms were reduced to once a week, then to once in 6 weeks, and finally they ceased altogether. The patient was employed as a salesgirl in a department store till the influenza epidemic, when an attack of influenza brought the paroxysms on again.

Case IV. (No. 5447).—Referred by Dr. Harold Goldburgh. M. McG., woman, 48 years old, single. Has had asthma for 15 years. Last 10 years attacks day and night. Chest on examination shows type I, complicated by chronic bronchitis and pleurisy. Urine repeatedly negative. Sputum repeatedly negative for tuberculosis. Skin reaction negative to many protein tests, but positive to pork, cabbage, rice, and radish, but the patient had these food principles excluded from her diet for the last 10 years. Patient had from 20 to 30 injections with no improvement, although after the third week the patient felt better for one week, but this was not lasting. The patient was discharged not improved on account of the severe bronchitis and pleurisy.

Case V. (No. 5408).—M. M., 41 years old, widow, no children, dressmaker. Has had a cough for 10 years, asthma 9 months; paroxysm nocturnal type. Physical examination of the chest shows type I. Urine examination repeatedly negative. Sputum repeatedly negative to tubercle bacilli. Blood pressure, systolic 160, diastolic 80. This patient had 20 injections, and in the second week began to improve; had no night attack; a cough in the morning and occasionally through day. The patient felt as though she never had any attacks and was discharged cured. Four weeks later she was caught in a rainstorm and developed an attack of influenza, having a temperature of 103° F., pulse 120. She came to the hospital with a return of her asthmatic paroxysm. Antipyretic and other routine measures were administered and she recovered in a week from her influenza. She was then given another 2 weeks of injection treatment and was discharged well.

Conclusion.—In a study of this series of 19 cases of bronchial asthma treated with vegetable nonspecific proteins I find no direct abortive effect in the paroxysm, but do find that the proteins apparently exert a certain distinct therapeutic benefit in certain cases of bronchial asthma, and I would suggest a further trial by other internists to ascertain definitely its therapeutic possibilities.

THE INTRASPINOUS TREATMENT OF NEUROSYPHILIS.

By CHARLES R. HUMBERT, M.D.,

KANSAS CITY, MO.

PATHOLOGIST, COLORED SECTION, KANSAS CITY GENERAL HOSPITAL.

AN attempt to upset the order of things established in any line of human endeavor is met with firm resistance on one hand and heralded with enthusiasm on the other. The collecting of evidence resulting from experimentation, etc., usually establishes a serviceable course to pursue. The introduction of the intraspinous treatment of neurosyphilis a few years ago caused quite a bit of restlessness among members of the profession. This has now subsided sufficiently to permit an unbiased consideration of the subject.

In order to ascertain in detail not only results, but the technique used, a circular letter was sent to some of the leading workers of the country. Thirty replies were received. They will be considered briefly.

Question 1. Do you use salvarsan? Yes, 100 per cent.

2. How often? Answers varied from every four days to every six weeks.

3. Which brand? Availability and price seemed to govern the choice. After giving about one thousand injections of the various brands I have been unable to determine much difference either as to toxicity or therapeutic value.

4. Do you use mercury? Yes, 100 per cent.

5. Mode of administration? Intramuscular, 90 per cent.; inunctions, 10 per cent.; 30 per cent. also added it to the serum.

6. Do you use intraspinous injections of serum? Yes, 60 per cent.

7. How often do you inject the serum? Answers varied from every four days to every six weeks.

8. What do you add to the serum? 30 per cent added mercury; 60 per cent used autosalvarsanized serum; 60 per cent tapped the spine at regular intervals. One of our leading syphilographers adds the salvarsan to the cerebrospinal fluid.

9. What results have you gotten from your method? Good, 70 per cent.

10. What do you consider improvement? 90 per cent clinical and serological, 2 per cent serological only; 8 per cent clinical only.

Summary.—The answers to the above circular letter tend to show a need for standardization along definite scientific lines as near as such can be done. The patient who gets plain serum intraspinously every six weeks cannot be said to be getting the same treatment as the one who gets salvarsanized serum every four days. Neither is the one who receives salvarsan added to the cerebrospinal fluid getting the same treatment as the one who has spinal drainage routinely and mercurialized serum. Differences in treatment make possible differences in results. The writer is convinced that this is, in part, the cause of the conflicting results equally enthusiastically reported.

Writer's Method.—This method is based on the following observations:

1. Barabat[1] has shown that thirty minutes after the administration of 0.4 gm. of salvarsan, 75 per cent is taken up by the body cells. Further, the serum contains five times as much arsenic as the clot.

2. The amount of salvarsan in the serum injected is too small to be of any value. It is the serum—immune bodies and foreign protein—that does the work.

3. Serum from blood drawn during the "reaction" is more toxic to typhoid organisms than that drawn at other times. I have observed in a few instances that the blood did not coagulate after withdrawal. The patient did not have hemorrhage from the puncture.

4. Akatsu and Noguchi[2] have shown that the *Treponema pallidum* can increase its tolerance to salvarsan 5½ times and to bichloride 35 to 75 times if we use these drugs in increasing amounts in media.

Technique: Massive doses of one drug with sudden shifts to others in order to prevent the organisms from gaining a tolerance is the object sought. The patient is placed on the table, salvarsan is made ready, then spinal drainage is instituted. This decreases the already increased pressure in the cerebrospinal fluid, permitting both mechanical and physiological passage of the drug through the choroid plexus and meninges before it is taken up by the body cells. The salvarsan is now administered intravenously. Wait a reasonable length of time for the "reaction." If it occurs draw off the blood then; if not, draw it off just the same and administer the serum intraspinally in the usual manner. The circulation of the cerebrospinal fluid makes subdural and intraventricular injections unnecessary.

Mercury is now started and rapidly pushed to the limit. Inunction, in my opinion, is the mode of administration, giving best results and causing no pain. The patients who are able are lined up in a circle; each rubs the one in front. There is a mistaken idea among too many physicians that in order to get the effects of mercury a few teeth, and occasionally portions of the mandible, must go. This is nothing short of malpractice. When there is evidence of salivation the blood is drawn and mercurialized serum is administered. The procedure is repeated until desired results are accomplished. The administration of iron, quinine, and strychnine tends to ward off the bad effects of the treatment. Throughout the course of treatment intraspinous injections are administered as often as shifts to the other drug are indicated, provided the physical condition of the patient permits.

Results: The number of cases treated thus far are not ready for report. Results, however, have been so satisfactory that I felt a preliminary statement justifiable. Many men object to this treatment on grounds that it is too drastic for the patient. It is not nearly so much so as the inevitable. The statement that the intraspinous treatment possesses nothing superior to the time-honored intensive method is not borne out by experimental or clinical data.

THE RELATION OF EYE AND EAR DISTURBANCES TO DISORDERS OF THE GASTRO-ENTERIC TRACT.

By JOSEPH KATZ, M.D.,
BROOKLYN, NEW YORK.

It is a well known fact, and yet neglected by even good gastroenterologists, that any disturbed condition of the eyes and ears may cause disorders of the digestive system.

It is my aim in this paper to impress and emphasize the importance of such examination or examinations as the case may be, as to the condition of the eyes and ears at the first presentation of the patient, to insure that the case is *primarily* a digestive disturbance and not an eye or ear underlying it, and treat accordingly.

To prove this fact and my contention, I shall cite a few cases taken at random from my files, in which the patients were completely cured of their gastric complaints by correction of the disturbance of their

eyes or ears, or both. These patients were under the constant care of physicians, both general practitioners and specialists, for years without obtaining the slightest relief of their distressing symptoms until I saw them and corrected the eye or ear disturbances.

Case I.—Miss C., aged eighteen, bookkeeper and general office clerk. Family history negative. Personal history: For the last two years patient has had severe headaches, disinclination to work, especially in the morning; nausea, constipation, pain in the epigastrium, appetite not as good as it had been; she is studious but cannot concentrate her mind on any one subject. She has been treated by several physicians, who told her that she had too much acid in her blood, and has been kept constantly on special diets and cathartics with no results.

Finally she was recommended to me and on examining her I found nothing pointing primarily to digestive disturbance. Lungs and heart were normal; urine examination showed marked indicanuria; analysis of the gastric contents did not disclose anything abnormal except slight increase in free hydrochloric acid. In examining her eyes the following was found: Vision of right eye, 18/20; left, 15/20. I advised her to consult an oculist, who confirmed my diagnosis and prescribed glasses. Patient reported three weeks later entirely cured.

Case II.—Miss S., single, operator at ladies' wear. Family history negative. Personal history: About four years ago began to have occasional pain in the right and left inguinal regions and epigastrium, menses normal, constipated, headaches, loss of appetite. The attacks of pain continued to increase in severity and frequency and, after consulting several physicians, she finally saw a surgeon, who diagnosed her case as one of chronic appendicitis, upon whom he operated with what seemed to be good results, but which only lasted three months. At the end of three months her condition became aggravated with vomiting, dizziness, and fainting ("as though to make up for lost time," the patient said). She kept on consulting physicians, also the surgeon who operated upon her, whose only suggestion was that another operation was advisable to relieve adhesions caused by the first operation. She was finally recommended to me and upon examination I found nothing in the gastrointestinal tract to cause her disorder except the adhesions, which contributed in part to her distress. Upon examining her eyes the vision of the left eye was 8/20, the right eye being normal. I advised her to consult an oculist, which she did, and reported five weeks later that she was entirely relieved except for an occasional pain in right inguinal region at the site of operation.

Case III.—Mr. B., twenty-eight, married, carpenter. Family history negative. Personal history: Has never been sick till now, but for the last two years has suffered from headaches, belching, constipation alternating with diarrhea, loss of appetite, loss of weight, nausea, and dizziness. Has been attended by private physicians and in dispensaries with no results. I saw him about four months ago and upon examination could not find anything anywhere to account for his condition; finally I examined his ears and found both ears full of cerumen mixed with dirt hardened into a mass which was difficult to remove. I advised him to consult an otologist, which he did, and after the removal of the foreign matter from his ears he was completely relieved, except for the irritation which these plugs had caused to the mucocutaneous membrane of the ears.

I could add to the above dozens of cases occurring both in private practice and in clinics, to illustrate the subject of my communication, but I think that even the few cases mentioned will be amply sufficient to prove my contention: "Examine the eyes and ears of every patient presenting for gastroenteric disorders."

287 Hinsdale Street.

Medicolegal Notes.

Board of Health's Power to Close Schools During Emergencies.—The Arizona Supreme Court holds that the power of the health board to determine whether an emergency exists for the making of rules and regulations and the adoption of health measures is administrative, and not legislative. In view of Arizona Civil Code 1913, pars. 4367-4404, an order by a city health board closing public schools during the rage of the late influenza epidemic, for the purpose of preventing the spread of the epidemic, was a valid measure, under paragraphs 4385 and 4370, subd. 3, authorizing rules and regulations "to prevent the spread of any contagious infectious, or malarious disease among persons." Necessity is the law of time and place, and the emergency calls into life the necessity for the operation of the law. The emergency calls forth the occasion to exercise the power to protect the public health. The court holds that while school trustees and educational administrative officers are invested with power to establish, provide for, govern, and regulate public schools within their respective jurisdictions, and are in these respects no wise subject to the direction or control of the state, county, or city boards of health, yet when the necessity arises to close the schools for the protection of the public health, such emergency, while it exists, is a superior power to that given the school administration officers, and the law of necessity controls the situation during the existence of the emergency giving rise to the power. The board's order, however, is effective only during the existence of the emergency.—Globe School Dist. No. 1 v. Board of Health of City of Globe (Ariz.), 179 Pac. 55.

Purpose and Application of Licensing Act.—The Illinois Appellate Court holds that a chiropractic who treats various diseases by manipulation of the vertebræ which contain the nerve centers of the particular portion of the body that is diseased and does not use any drugs is engaged in the practice of medicine so as to necessitate the procurance of a license under the Illinois statute, providing that any "person shall be regarded as practising medicine . . . who shall treat or profess to treat, operate on or prescribe for any physical ailment or any physical injury to or deformity of another." In an action against one practising as a chiropractic without a license to recover the statutory penalty, an instruction that if the jury believed "by a preponderance of the evidence that the defendant did not practise medicine, but that his acts were, in fact, an adjustment of the human body for the purpose of adjusting the spinal column or other organs for the nerves for the purpose of causing the blood to flow freely, and by so doing that the blood would flow freely, and thereby the cause be removed, then the defendant would not be guilty of practising medicine in violation of said statute, unless he held himself out or advertised himself as a doctor or physician," is erroneous.

In discussing the purpose of the licensing statute the court said: "It undoubtedly, as the evidence of the doctor shows, requires skill to be able to determine what the disease is and what particular manipulation is required in order to effect the cure, which undoubtedly requires skill and learning along these particular lines, and the very object to be accomplished by this statute is to prevent persons who are not possessed of such skill, or who do not understand the human system and the mode of treating, from practising upon afflicted people. Even though the appellee may have fully understood these matters, as he claimed, yet another person without the education might undertake to operate upon and treat different persons for their various afflictions without in fact knowing what the real trouble was, or whether by the particular act or treatment a cure will be effected or the person injured thereby. Very few of the people who have not given such matters a careful study would be able to determine before employing such as to whether they had the ability or not, and the object of this statute is to provide that no one shall be allowed to practise medicine or operate upon or profess to treat persons without they have the requisite knowledge so to do, and this is to be determined by a competent board appointed by the state."—People v. Black, 211 Ill.

TUBERCULOMATA OF THE SPINAL CORD.

THE tubercle, the most frequent variety of intramedullary tumors, is most commonly met with in males from 20 to 40 years of age. The morbid process is more prone to occur in the dorsolumbar segment of the cord, preferably in the gray matter. Contrary to the classical descriptions which give a clinical picture of tubercles of the cord in general, it is necessary to divide these lesions into three distinct types, the first of which is tuberculoma of the dorsal region, which at the outset produces a typical Brown-Séquard syndrome in some cases and ends in a spasmodic paraplegia with a more or less complete anesthesia. Secondly, the tuberculoma of the lumbar cord, beginning with painful and atrophic phenomena in one leg, thus simulating a serious form of sciatica and ending in a limp atrophic paraplegia with anesthesia and paralysis of the sphincters. Thirdly, tuberculoma of the cervical expansion, the début of which is also manifested by painful and atrophic phenomena, but these are limited to the arms, while the tuberculoma, continuing its evolution, gives rise to a homolateral spinal hemiplegia, with or without Brown-Séquard's syndrome and ending in a complete spasmodic paraplegia with anesthesia reaching to the upper part of the trunk. In some cases bulbar phenomena appear.

During the evolution of a tuberculoma of the cord the sensitive disturbances offer a radicular topography, whether or not they extend to one-half or the entire body. They have a certain predilection for thermic sensibility. They may also assume sensibility to pain of the syringomyelic type, which can be explained by the localization of the tubercle in the gray matter between the anterior and posterior horns.

Although in intramedullary tumors radicular phenomena have been regarded as rare, it would appear that tuberculoma offers an exception in this respect, because certain forms, particularly those of the enlargements of the cord, have a distinctly radicular phase—pain and atrophy. In one case the explanation of the importance of these radicular symptoms was given inasmuch as there was a true infiltration with degeneration of the anterior and posterior roots (Ackerman, Thèse de Paris, 1914).

Ackerman has, like most other writers, noted the great frequency of unilateral development of the tubercle. Even when it reaches very considerable size one-half of the cord will be found to be pushed aside, but it is normal. This is in accord with the clinical evolution, because the symptoms are unilateral and also on account of the possibility of a predominance of disturbances on one side until the end of the affection.

Although meningeal lesions are common they are, in these cases, usually secondary to the process in the cord. In one case they consisted of a true pachymeningitis, while in another instance of tuberculoma of the cord there was a tuberculous lesion of the spine, although there was no immediate relationship between the two processes, the bone lesion being seated in the first lumbar vertebra, the tuberculoma occupying the fourth and fifth dorsal segments. In all cases of tuberculoma of the cord pulmonary or suprarenal tuberculous lesions are present. The tuberculoma offers different histological aspects according to the case. It may be in the form of an agglomeration of follicles or as a compact caseous mass. Giant cells may be found, but Koch's bacillus is apt to be absent in the sections.

HEMOGLOBINURIC BILIOUS FEVER OF TROPICAL COUNTRIES.

HEMOGLOBINURIC bilious fever of warm climates is above all met with in malarial districts. It is now generally admitted that it attacks almost exclusively paludal subjects who have long lived in the country and have tropical anemia. This explains why this morbid process is very rare in malarial regions on the Mediterranean coast where the climate is temperate and allows the subject to recuperate from organic wear for several months in each year, an impossibility in tropical climes. In malarial subjects the immediate cause of the hemoglobinuric syndrome may be an acute return of the malaria, but what is far more common is that the principal cause will be either the action of cold, intoxication from food, or overwork.

It has been demonstrated beyond a doubt that the hematozoon is capable of breaking through into the kidney, creating the lesions of infectious nephrites with hematuria and bilious phenomena. The old accepted denomination of hematuric bilious fever should be retained and should not be allowed to disappear from our present ultramodern nosology. In reality this morbid process merely represents a very rare variety of paludal infection. From renal hematuria to hemoglobinuria the distance is short and in point of fact both symptoms may coexist in the same subject in which circumstance the case should be labeled hematohemoglobinuric bilious fever.

A third and more serious variety may be qualified as absolute hemoglobinuric bilious fever. This process is the result of a very extensive destruction of

the red blood corpuscles by the hematozoon and its toxins. To this malarial hemoglobinemia a splenorenal hemolyzing action becomes added, as well as that of all cells susceptible of performing phagocytosis.

If a hemoglobinuria due to quinine exists, it must not be mistaken for a hemoglobinuria of warm climates. The former is unquestionably most uncommon in tropical countries because, since the general use of prophylactic quinine treatment it should logically be more frequent than formerly, when in reality its decrease seems rather to be in direct ratio with the increased prophylactic consumption of quinine and also with the general measures now carried out for prophylaxis of malaria in all warm climates. It has also been demonstrated experimentally on animals that quinine does not produce hemoglobinuria.

The prophylaxis of hemoglobinuric bilious fever is the same as that of malaria, while in the treatment of the paroxysms the exhibition of quinine should be reserved to mild cases or those of medium intensity. The treatment of hemoglobinuric bilious fever should above all aim at reestablishing the functions of the emunctories by diuretics and injections of isotonic or hypertonic sera. This treatment is to be completed by an adjuvant medication, variable according to the case and of a tonic and stimulating nature, as the main object is to improve the general physical condition as rapidly as possible.

THE UNICISTIC VIEW OF INFLUENZA.

It is inevitable that a school of clinicians will in the future insist that all influenza is one and the same malady whether sporadic, endemic, epidemic, endemic, limited epidemic, or pandemic. It is not necessary that the exciting cause be always the same. Several organisms may set up the same picture or two may form a symbiosis. It is possible of course that a filtrable virus is back of it all, just as years ago such a virus was shown to be a cause of ordinary colds; in such a case the various exciting causes may be shown to be secondary. The transmissibility may vary from *nil* in sporadic and massed endemic cases to slight in epidemico-endemics and pronounced in pandemics. It has been shown of the pandemic of 1889-90 that nearly one-half of practitioners who attended the cases were opposed to the idea of contagion from person to person. The converse came to be admitted of the recent pandemic, for most authorities arrived at the conclusion that the disease was frankly transmissible with about two days incubation.

High diffusibility stands in no relation to mortality, for in the countries attacked by the early spring and summer wave the mortality was usually light. It was the return wave in these countries and the autumn wave in the others that were deadly. Yet alongside of the pneumonic scourge we constantly saw every milder degree of influenza. Conversely in the milder pandemics and limited epidemics we saw in the background the same fulminating pneumonias and toxic or septic cases but in greatly reduced percentages. While the bronchopneumonias of influenza may be *sui generis* or at most suggest the same complication in measles and pertussis, the vast number of ordinary croupous pneumonias in the recent pandemic suggest the ordinary cold weather affection endemic with us, which exceptionally appears in epidemic incidence.

Dr. Bemelmans, a Dutch veterinary, contributes a note to the *Nederlandsch Tijdschrift voor Geneskunde* for September 20, in which he strongly upholds the unicistic view and incidentally claims that human endemic influenza is the same affection as the contagious lung plague of horses. He therefore thinks it feasible to prepare a horse serum by the inoculation of animals with diplostreptococci and pneumococci which should immunize against and cure human influenza, upon the theory that to these germs is due the mortality of the disease.

RECENT ADDITIONS TO OUR KNOWLEDGE OF TYPHUS.

This affection, like its namesake of a century ago, which was finally disassociated into typhus and typhoid, is now in further danger of losing its autonomy. The differences in the bacteriological finds have forced the conclusion that typhus, like typhoid, may be a syndrome rather than an autonomous affection. However this may be, it now seems assured that a protozoan, the Rickettsia, can set up a specific infection which goes by the name of typus and is louse-borne. In *La Presse Médicale* (September 25, 1919, xxvii, 54) Fourcade shows the completeness of the chain of evidence of a protozoan typhus. All of the data make for the existence of this affection but nothing is adduced in disproof of the pathogenicity of the numerous other microorganisms accused from time to time. In other words the dualistic view is not overturned in the article cited, although the pathogenetic properties of the Rickettsia have been shown for Servian, North African, and Mexican typhus and other national forms, which fact of course weakens the dualistic hypothesis. The Rickettsia as a matter of fact represents a genus, another species of which, also louse-borne, may be responsible for Volhynia fever, while still other species which inhabit lice are not known to be pathogenic. The questions of early diagnosis, prophylaxis, and perhaps of serotherapy are at present bound up in the thesis that typhus is due to this organism, and this seems to leave no room for dualism in practice. On the other hand typhoid fever was once made synonymous with the lesions due to Eberth's bacillus, only to be shown later to be a group of diseases, and a like fate may attend on any supposed pathological entity to say nothing of the possibility that the alleged pathogenic microorganism may prove to be active only in secondary infection. In the same number of *La Presse Médicale* is an article on the nervous complications of typhus by Paulian. The nervous system is as it were sensitized by the first explosion of the disease and the number and variety of nerve lesions which may or may not develop is large, affecting both the central and peripheral organs. Constant for all cases is a meningeal reaction, the effects of which may persist for a year or more.

Palilalia.

This phenomenon, called also paliphrasia, is said to have been first isolated by Souques in 1898 and during the present year it has been made the subject of a graduation thesis by Kagane which is reviewed in the *Journal de médecine et de chirurgie pratiques* for August 10. At first sight and to an amateur in psychiatry it seems at least very closely related to echolalia, since it is said to consist of meaningless repetition of a word or word combination, but the repetition is that of the person's own words and not, as in echolalia, those of another. This repetition is involuntary and spontaneous, but conscious and incurable. When the patient is asked why he does this the answer is that the impulse is too strong to be overcome. It is more or less frequently associated with other compulsive behavior, as laughter and weeping, spasmodic speech, and dysarthria. Usually the mental state is one of progressive enfeeblement. In a few cases it has existed side by side with echolalia, echopraxia, and echomimia. Thus far it has been seen only in organic disease in the right or left cerebral hemisphere, more definite location having not yet been determined. The author correctly limits the term echolalia to the repetition by patients of words spoken by others, but some neurologists have included the so-called palilalia under the general term echolalia. A paralytic who always replied in staccato voice "is that so?" three times when told any piece of news, was characterized as an echolalic by a well-known psychiatrist.

Nature of Pregnancy Toxicoses.

In a discussion of a paper on this subject, read before the last session of the German-Swiss Gynecological Society (*Correspondenz-Blatt für Schweizer Aerzte* for August 21), Professor Labhardt announced that in all of the conditions classed under pregnancy toxicoses certain chemical substances could be recovered from the serum. These have a more or less marked vasoconstrictor action. The substances in question are doubtless amines, but this is difficult of proof because there is no chemical reagent for the group nor is there a biological test. A separate line of investigation makes them proteinogenic amines—the type found in the protein molecule as pre-existent. Guggenheim, who has worked along these lines asserts that hormones themselves are amines which originate from the higher albumins through decarboxylization. At present we are unable to follow up the subject of the identity of the two classes of substances, but there is an inviting opening for future research.

News of the Week.

Physicians Refuse to Act Under Industrial Compensation Board.—The Colorado State Medical Society, at its annual meeting on October 10, passed a resolution refusing to accept any cases protected by the State Industrial Compensation Fund, unless it was agreed that the standard fee would be paid. It is claimed by the doctors that the fees provided by the commission are 50 per cent. lower than the regular fees paid by the public at large. The physicians maintain that since every doctor does a certain amount of charity work they have a right to set their own fees.

Washington Physicians Raise Fees.—The Spokane Medical Society and the Yakima Medical Association have taken steps to increase their fees. The latter organization has adopted a new scale of prices, whereby office and telephone consultations have been advanced from $1.50 to $2; city day calls from $2.50 to $3.50; night calls from $5 to $7.50, and obstetrical cases from $25 to $35. The Spokane Medical Society proposed a schedule of fees raising office calls and simple consultations to from $3 to $5, house calls to $4, and other services in proportion, but after discussion it was decided to abolish all fee bills and to raise prices commensurate with the high cost of living and equipment.

Nurses May Raise Rates.—A special meeting of nurses was held in Macon, Ga., to decide whether or not to raise their rates from $5 to $6 a day. As there was considerable difference of opinion as to the wisdom of this advance no definite action was taken.

Red Cross Will Keep Base Hospitals.—New York's eight Red Cross base hospitals, which were of such value during the war, are to be held intact for future emergencies, such as floods, earthquakes, epidemics, etc. The eight New York City base hospitals were organized at the following institutions, from most of which assurance has been received that they will be kept intact for any emergency: Bellevue Hospital, Presbyterian Hospital, Mt. Sinai Hospital, New York Post Graduate Hospital, New York Hospital, Lenox Hill Hospital, and the Metropolitan Hospital.

New York Hospitals Seek $1,000,000. — The United Hospital Fund, which contributes to the maintenance of forty-six hospitals in New York City on the basis of the number of days of free hospital treatment given, announces that during the week of November 17 an intensive campaign will be carried on to raise $1,000,000 to help meet the deficit of $3,000,000 recently reported from these hospitals. The money will be apportioned by a committee headed by the Mayor, and composed of the presidents of the Chamber of Commerce and the Merchant's Association and other members of the executive board of the United Hospital Fund. The report shows that the hospital facilities of the city are lacking to the extent that 2,000,000 persons who were in need of hospital care failed to receive it in 1918, and that only one person in ten seriously ill in the city is getting hospital care.

Pneumonia a Reportable Disease.—Dr. Hermann M. Biggs, Commissioner of Health, has sent an open letter to the physicians of New York State reminding them that the Sanitary Code requires that all cases of pneumonia shall be reported to the local health authorities as soon as the diagnosis is made, and that in the reports lobar and bronchial pneumonia should be differentiated.

Mobile Child Welfare Station.—The Westchester Chapter of the American Red Cross has equipped a model child welfare station in the interior of an auto truck and has sent this exhibit into a large number of the towns in Westchester

county. When it arrives in a community it is placed under the direction of the local public health nurse, the State and county health nurses acting as her assistants. In this way a great interest is stimulated in child welfare and other forms of public health work. Meetings are held in the evening at which health films are shown. The health officer of the community is the speaker at these meetings and other professional workers give five-minute talks. Little Mothers' Leagues have been organized in nearly every town visited.

British Surgeons Receive Distinguished Service Medals.—At the convocation of the Clinical Congress of American Surgeons, on the evening of October 24, Major General Ireland conferred the Distinguished Service Medal on Sir Anthony Bowlby of London and Sir Robert Jones of Liverpool.

Dr. Henry A. Christian, Hersey Professor of the Theory and Practice of Physic at Harvard University, has assumed the position of Chairman of the Division of Medical Sciences of the National Research Council.

Dr. Matthias Nicoll, Jr., has been appointed a member of the Advisory Committee of the International Exposition of Municipal Equipment, recently established in Grand Central Palace, New York.

Dr. Fred Towlsey Murphy, who recently resigned as professor of surgery at the Washington University Medical School, St. Louis, has been chosen a member of the medical faculty of Yale University.

Dr. Charles E. Smith, Jr., has been elected secretary of the State Board of Health of Minnesota.

Dr. Jose Castillo, Jr., of Sao Paulo, Brazil, is visiting New York for the purpose of studying hospital organization.

Dr. George D. Arnold, after having served thirty years as chief medical examiner of the Voluntary Relief Department of the Pennsylvania Lines West of Pittsburgh, has been placed on the honor roll of retired employees. He was recently tendered a farewell dinner at Fort Pitt Hotel, Pittsburgh, and presented with a handsome gold watch by the Medical Corps and others closely associated with him in his office. Dr. Herman Heston, medical examiner at Columbus, Ohio, will succeed Dr. Arnold, with headquarters at Cleveland. Dr. S. M. Humphreys has been transferred to Columbus, and Dr. L. W. Brown, assistant medical examiner at Cleveland, has been appointed medical examiner at Grand Rapids.

Dr. Henry L. K. Shaw, formerly director of the Division of Child Hygiene, has been made a consultant of the New York State Health Department.

Gifts and Bequests.—Mrs. William Douglas Sloane has given $5,000 to the building fund of the Hilcrest Hospital in Pittsfield, Mass.

J. Pierpont Morgan has presented the Hartford Hospital, Hartford, Conn., with a gift of $50,000, which brings the endowment fund of that institution to over $500,000.

Women Doctors Organize.—At the conclusion of the International Conference of Women Physicians, which was in session in New York City from September 15 to October 25, the women physicians of the world established a permanent organization the purpose of which is to promote closer association among the women doctors of the world. The society has elected the following officers: *President,* Dr. Esther Lovejoy, New York; *Vice-Presidents,* Dr. Christine Murrell of London, Dr. L. Thrillier-Landry of Paris, and Dr. Kristine Munch of Christiania; *Corresponding Secretary,* Dr. Martha Welpton of San Diego, Cal.; *Recording Secretary,* Dr. Marie Feyler, Lausanne, Switzerland; *Treasurer,* Dr. Ellen C. Potter, Philadelphia.

Opposition to State Health Insurance.—Resolutions opposing compulsory health insurance were adopted by the Medical Society of the County of New York at its meeting on October 27. The twenty-three delegates to the State Medical Society were instructed to vote against the measure and substitutes that may be offered for it when the delegates meet at Albany November 22 to discuss the question.

Journal des Sciences Médicales de Lille.—On October 5 the first number of this journal to appear since August 1, 1914, was issued. We congratulate our contemporary on its reappearance, thereby signalling the triumph of right and justice over the savagery of the brutal hordes that so long held the city of Lille in their power.

Red Cross Opens "Health Flat."—The Red Cross has opened an apartment at 418 West Twenty-ninth Street, New York City, where the women of the district, chiefly the wives of dockmen and factory operatives, will receive free instruction in home nursing and a general course in cooking. The school will be a part of the peace program of the relief organization.

Report of Child Health Organization.—This organization, which is under the direction of child specialists, public health men, and educators, is making an appeal for funds. Its first report just issued states that 10,000,000 children in thirty states have had their monthly weight records kept and are being instructed in health habits. Three of the largest cities in the country have placed scales in all their public schools. More than 800 public health, social and educational bodies are pushing this child health program. The report states that there are 6,000,000 children under weight in the country and urges the importance of bringing these children to proper condition. Dr. L. Emmet Holt is Chairman of the Executive Committee.

The Diagnosis of Meningitis.—The New York City Health Department in a recent Bulletin calls the attention of physicians to the fact that the Meningitis Division of the Research Laboratory of the Department of Health is prepared to send one of its members to consult with them on cases of suspected meningitis or other meningeal involvement. Cases are not seen without the physician in charge being in attendance. Lumbar puncture will be performed if it is advisable, and serum will be administered if it is indicated. The desirability of making an early diagnosis in cases of epidemic meningitis is strongly emphasized.

Dr. Siegfried Block announces his removal to 502 Washington Avenue, near Gates Avenue, Brooklyn, N. Y.

Dr. Albert R. F. Anderson announces his removal to 88 Sixth Avenue, Brooklyn, N. Y.

Obituary Notes.—Dr. HERMAN E. STREET of Brooklyn, a graduate of the New York Homeopathic Hospital, in 1892, died following an operation for peritonitis in the Peck Memorial Hospital, on October 20, aged 73 years. He was a member of the New York State Homeopathic Medical Society and visiting dermatologist to the Cumberland Street Hospital.

DR. LOUIS JOSEPH ROY, a graduate of Laval University Medical Department, Quebec, Canada, in 1880, died at his home in Indian Orchard, Mass., on Sptember 30, aged 61 years.

DR. WM. H. TOUSLEY died at Philadelphia on September 11. He was graduated from the Tulane University of Louisiana School of Medicine in the class of 1888.

DR. JOHN A. HEARST died of heart disease at Philadelphia, on October 4, at the age of 48 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1893 and he served as intern in the Germantown Hospital. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

DR. GEORGE W. PARKER died at Philadelphia of apoplexy on October 5, at the age of 80 years. He was graduated from Hahnemann Medical College and Hospital of Philadelphia in the class of 1870.

DR. WM. ADAM SEIBERT died at Easton, Pa., on October 7 at the age of 61 years. He was graduated from the Boston University School of Medicine in the class of 1885. He was a trustee of the State Hospital at Rittersville, Pa.

DR. CHARLES W. FOX of Philadelphia, died on October 8 at York Harbor, Maine, at the age of 76 years. He was graduated from the Long Island College Hospital in the class of 1865.

DR. DAVID B. VAN SLYK, formerly of Brookline, Mass., died at his home in Pasadena, on October 1, aged 90 years. He was a graduate of the University of Buffalo Medical Department, in 1852, served through the Civil War with 101st New York Infantry and the 22nd New York Cavalry, and was at one time president of the Southern California Medical Society.

Dr. JAMES B. DINNAN, superintendent of the Meriden (Conn.) State Tuberculosis Sanatorium, died of pneumonia following typhoid fever, at his home in Meriden, on October 3, aged 38 years. He was a graduate of Yale Medical School in 1904.

Dr. CYNTHIA A. SKINNER of Los Angeles, Cal., a graduate of the Northwestern Women's Medical School, Chicago, in 1890, was killed instantly when her automobile collided with a street railway car, on October 3. She was 55 years of age, and formerly practised in Burlington, Ohio.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON October 3, 1919.

Venereal Disease.—While there is no agreement as to the best method of dealing with the menace of venereal disease, there is complete agreement with regard to its existence on a wide scale. Perhaps readers of these letters may think that too much space is devoted to a consideration of the venereal problem, but it is the fact that at the present time it is the most important question from the medical standpoint. In Great Britain lay and medical journals are full of the subject. Scarcely a day passes that a medical man does not contribute to a paper a letter dealing with one phase or other of the matter. Argument hinges most on the prophylactic or early preventive treatment and the views of its supporters and opponents are freely ventilated. Recently there appears to have been a strong attempt on the part of the opponents of these methods to convince the public that their value is wholly problematical and that to introduce them among the civil population would be in a high degree detrimental to the general health of the community, not to mention subversive of morality. Among those who argue in this fashion is Dr. Hugh W. Baly, in the *Daily Telegraph* of Sept. 27, who deprecates what he terms the attempt to force the medical profession as a whole to pronounce a verdict which many feel is contrary to scientific evidence and the health of the nation, and is disposed to dispute the claim that true morality is best shown by permitting disease, suffering, and racial suicide to progress when an efficient protection is at our disposal. The writer goes on to say that steps have been taken to lay before the public the opinion of those who hold that cleanliness is next to godliness and says that, personally, he thinks that the medical profession will be guilty of a grave error in judgment which will have harmful results in the future, and which may reduce public confidence in the medical profession if, for any consideration of temporary expediency or diplomacy, they withold any truth from the public touching any matter in regard to the prevention of disease. For over ten years the writer states that he has especially interested himself in venereal disease and he wishes strongly to give it as his opinion that he does not consider fear of infection as practically of any value as a deterrent of sexual irregularity. He holds that the statement that the provision or accessibility of personal disinfection packets will increase sexual irregularities is entirely false, a bogey that has no real existence. Both sides of the question have been presented to the public up to a certain point, but details have been withheld with respect to prophylactic treatment. It now appears that such details will be furnished shortly in a lay journal of wide circulation. Whether this will be for the ultimate good of the public it is difficult to say. It is a matter on which it would be extremely rash to pass judgment. This much, however, is known that venereal disease is prevalent everywhere, greatly more prevalent than before the war, and that it is in the interests of the race that its ravages should be checked.

Consultative Councils of the Ministry of Health.—From the first, it was made clear in the Ministry of Health Bill that when the Ministry was established it would seek advice on a variety of subjects within its province from advisory bodies selected with the view of including men and women with full practical knowledge of the questions on which they would be asked to advise. These bodies are termed in the act Consultative Councils. In the case of England they will be four in number and will consist of the Consultative Council on Medical

and Allied Services, the Consultative Council on National Health Insurance, the Consultative Council on Local Health Administration, and the Consultative Council on General Health Questions. The councils will consist of twenty members each, including a chairman and vice-chairman, but they may for special purposes appoint committees on which other persons may be co-opted, so that particular problems will be considered with the help of those who have made them a special study. The membership of the Consultative Council on General Health, which will also be twenty in number, is not yet completely settled, but at least half of its members will be women.

To the Consultative Council on Medical and Allied Services will be referred such problems as the national development and extension of medical, nursing and midwifery work, and it is proposed that for some purposes it should, in accordance with the arrangement outlined above, act through committees more specialized than the council itself. Its members have been chosen from the ranks of specialists in medicine and surgery of general practitioners both private and insurance, from the public health services, from women who work in medicine, especially in the case of mothers and infants, from the fields of hospital administration, and from the ranks of those who apply other branches of science to medicine. It is intended that when questions are under consideration that specially affect the nursing and midwifery services of the country, the council shall be assisted by the appointment of a committee consisting partly of its own members, but also including practising nurses and midwives and other persons, not members of the council, who have devoted themselves specially to the study of nursing and midwifery questions. The chairman of the council will be Sir Bertrand Dawson, physician to the London Hospital, Dean of the Faculty of Medicine, University of London, the members of the council will be men and women distinguished in medicine and surgery in preventive medicine and so on.

The Consultative Council of National Health Insurance, as its name denotes, will consider problems of approved societies' work arising in the administration of the cash benefits, sickness, disablement, and maternity, by approved societies under the Insurance Act.

The Consultative Council on Local Health Administration will consider the administrative problems arising out of proposals for the development and extension of health services, and its membership has been composed so as to include persons familiar with the work of local authorities of various types, the insurance committees, and the poor law guardians.

In the case of Wales there will be one consultative council consisting of thirty members. It will give advice and assistance in connection with such matters as relate to national health insurance, medical and allied services, local health administration, and general health questions in Wales and Monmouthshire.

Annual Report of the Chief Inspector of Factories and Workshops.—In this report, issued recently, there are important chapters on hours of work, accident prevention and safety first, welfare, ambulance and first aid continuation classes and industrial poisoning. The chief inspector in his introduction says: "The prominence given to safety, health, and welfare, including reduction in the hours of labor, have perhaps been, apart from the special war work, the principal feature of the work of our department not only during the past year, but also during the whole period of the war. The experience gained had great effect upon the conditions of industrial employment. It has shown that an increase in the ordinary hours of work does not necessarily mean an increase in production, that the more the comfort and welfare of the worker is studied and provided for the greater is his output, and that attention given to health and the prevention of accidents means greater efficiency and reduced charges.

It is pointed out that few questions affecting the industrial worker have been brought more prominently forward during the war than that of welfare. Long before 1914 there had been an increasing desire on the part of enlightened individual employers to improve the conditions of employment in their works beyond the statutory requirements, and much had been done to encourage and extend this desire. The strain thrown upon all engaged in the manufacturing industry during the war rendered immediate attention to the health and welfare of the worker absolutely essential, and the improvements brought about were largely due to: (1) The conditions attached to the emergency orders issued by the Home Office relaxing the statutory periods of employment. (2) The reports and memoranda issued by the Health of Munition Workers' Committee. (3) The establishment of a welfare section in the Ministry of Munitions, and (4) The authority which was given to the Home Office by the Police Factories Act of 1916 empowering the office to make welfare orders.

Increased Infant Mortality.—In the Registrar General's Report for England and Wales for the quarter ended March 31 last, it was stated that the infantile mortality rate was 149 per 1000 births, or 31 per thousand more than the average for the ten preceding first quarters of the year, and 53 per 1000 above the average for 1917. In a report published recently by Dr. F. G. Haworth, the medical officer for Darwen, Lancashire, it is pointed out that such a rise if continued is very disquieting, especially when considered in relation with the loss to the nation from a lowered birth rate in face of an increased marriage rate. For the first time in British statistical history natural increment has ceased to exist. During the six months ending March 31 last, the deaths in England and Wales exceeded the births by 126,445. The babies born during the quarter to the end of March were 17,388 fewer than in the corresponding quarter of 1918, and this in spite of the fact that in the whole of that year the total number of marriages in England and Wales were the highest on record, except in the year 1914-15. According to Dr. Haworth this decrease of births cannot be explained by the enforced separation of husbands and wives, but must be explained by the increased use of "birth-control" methods, seeing that the number of marriages was above the normal. The rate of still births was double in the case of unmarried mothers.

1. Significance of Arrhythmia in the Infections of Childhood. Clifford B. Farr.
2. The Ideal Sanatorium, the Ideal Physician, the Ideal Nurse, and the Ideal Patient. S. Adolphus Knopf.
3. Malignant Neoplasms of the Thymus Gland. Spencer G. Strauss.
4. Gastric Disorders as an Early Sign in Pulmonary Tuberculosis. Joseph Katz.

1. Significance of Arrhythmia in the Infections of Childhood.—Clifford B. Farr, in common with the majority of his colleagues, received his first ideas of heart diseases at the beginning of the present century, when the attention of the profession was riveted upon the physical signs and symptoms of loss of compensation. In the succeeding years he gradually became cognizant of the views of the cardiac mechanism championed by James Mackenzie, Wenckebach, Einthoven and Thomas Lewis. The problem, however, was not presented to him in an acute form until he was confronted by hundreds of cases of diphtheria and saw children constantly dying from cardiac failure, with few if any of the manifestations of ordinary valvular heart disease, but presenting variations in the frequency and rhythm of the pulse (bradycardia, irregularity) the significance of which was not entirely clear to him nor easily translatable into present day terms. What was the prognostic meaning of these pulse changes? Bound by tradition, were we not attaching too much significance to simple irregularities and overlooking others of grave import? This possibility was his excuse for gathering the scanty information of a positive nature to be found in the literature and trying to determine what light it might throw on the diagnosis and prognosis of the circulatory complications of diphtheria and by analogy on the diagnosis and prognosis of similar complications in other infections of childhood. Passing over the discussion in detail of the classification and methods of recognition of the arrhythmias of childhood, Farr enumerates the important forms and discusses briefly their incidence in childhood. The principal forms of arrhythmia, according to Lewis, are: Sinus irregularities, heart block, premature contractions, simple paroxysmal tachycardia, auricular flutter, auricular fibrillation, and alternation of the pulse. Only the first three types mentioned have been repeatedly encountered in diphtheria. After considering these and giving a table of cases of heart block, etc., in diphtheria, culled from the literature, the writer summarizes his observations as follows: Sinus arrhythmia is of no prognostic significance in diphtheria. Premature contractions are of uncertain significance but may suggest beginning myocarditis with increased irritability. Heart block of all degrees implies toxic injury or inflammatory infiltration of the conducting fibers. It frequently accounts for the sudden and ominous fall of the pulse rate in diphtheria. These forms of arrhythmia may be variously combined. Auricular fibrillation is rare in diphtheria. Auricular fibrillation (formerly called nodal rhythm, pulsus irregularis perpetuus, etc.) is the most important of the purely pathological arrhythmias. It is never to be lightly regarded and is generally of serious prognostic significance. It is common in failing hearts of chronic endocarditics (rheumatic or otherwise) in adolescence and in adult life. It is not, however, a frequent finding in diphtheria and other acute infections. He found it described in association with extra systoles (nodal) in two cases (by Hume) and in two cases (one each by Price and Mackenzie and Parkman) in association with heart block. In auricular fibrillation the distended auricles do not contract but quiver rapidly under the influence of a rapidly recurring series of fruitless impulses. The ventricle is unable to respond uniformly to these tumultuous stimuli nor yet to assume its own pace as in heart block. As a result it contracts in a totally irregular fashion, abortive, weak and strong beats succeeding each other rapidly in hopeless confusion without any semblance of fundamental rhythm. If a condition of impaired conduction or heart block is induced by drugs of the digitalis group, the pulse becomes slower and often quite regular though the condition of the auricles is unchanged. Auricular fibrillation may be temporary as in acute infections (toxic) but is usually permanent and indicates serious myocardial weakness or exhaustion. In diphtheria it may be due to a toxic injury to the myocardium, possibly temporary, or to antecedent cardiac disease. Pulsus alternans, one of the rarer forms of irregularity, is characterized by alternate strong and weak beats at equal intervals (in contrast to bigeminus) and is indicative of serious myocardial weakness. It has been seldom or never observed in childhood and no cases of this type or arrhythmia have been recorded as occurring in diphtheria. Auricular flutter, one of the rarer forms of arrhythymia, is characterized by an extremely rapid pulse (300-550) though with regular contraction of the auricles as registered by the electrocardiograph. It is one of the causes of paroxysmal tachycardia. Frequently the ventricles contract at a much slower but regular rate, due to a condition of partial heart block. In other instances auricular fibrillation is simulated. Hume reports one case of paroxysmal tachycardia associated with auricular flutter occurring in diphtheria. In this case recovery followed.

4. The Intraintestinal Tube Treatment of Hookworm Infection.—John L. Kantor recommends the intraintestinal tube method as the method of choice for the cure of hookworm infection, on the ground that it is more efficacious, safer and, once the duodenal bucket is in place, quicker than the methods at present in vogue. He has treated over 250 cases by this procedure, which consists of the introduction of the duodenal tube, the injection of oil of chenopodium through the tube, and the injection of a saline flush to prevent toxic asorption of oil. The evening before treatment, the patient is given a light supper. There is no preliminary catharsis. The next morning the duodenal tuber is swallowed on a fasting stomach, and the patient is kept on his right side until the bucket has passed the plylorus. This is determined by the recovery of a Congo-negative bile and by the fact that water injected into the tube cannot be recovered because it flows into the intestine. The oil of chenopodium, in 3 c.c. dose, is then injected into the tube with a 30 c.c. syringe and followed by the injection of air to insure the explusion of the entire dose from the tube. It is possible that 2 c.c. may be sufficiently potent. Six minutes is allowed for the diffusion of the oil through the worm-bearing area. At the expiration of this interval two to three ounces of a warmed solution of magnesium sulphate are injected transduodenally, the object being to prevent toxic absorption of the oil. The specific toxic effects of drugs can be studied under the precise conditions of tube

treatment. Oil of chenopodium seems to have a selective action on tissues sensitized by previous disease or injury.

2. **Results of the Modern Treatment of Diabetes.**—Henry Rawle Geyelin reviews the therapeutic results that have been obtained with the Allen treatment for diabetes during the past four years, and makes comparisons with the results obtained by the older methods of treatment. He finds that probably the most striking result of this comparison in the great increase in the number of patients discharged free from sugar and ketone bodies. The writer concludes as follows: 1. Diabetes in its severe and acute form is not limited to the first three decades of life, but may be found at any age, although rare in persons over 30. In my experience it is more common between 50 and 70 than between 30 and 50. 2. Absolute adherence to the diet is essential to a maximum degree of successful results in treatment. Without there is no hope unless the diabetes is very mild; and even in that case there is great risk of it becoming severe. 3. Fast days and half days are of great help in treatment of the majority of patients, but are not necessary as routine measure in all cases at all times. 4. It is wise for a patient under treatment to realize that he is not a normal person on a normal diet and to regulate his mental and physical activities, and, therefore, his caloric output, by his caloric intake. 5. Exercise should be advised only in exceptional cases and in proportion to the amount of energy afforded by the caloric intake. Rest rather than exercise should be urged. 6. Long continued diets overbalanced in fat (180 gm. and over) are harmful, and their harmful effect is insidious. Aside from their immediate effects in the production of acidosis and glycosuria, they have a depressing effect on tolerance. This effect is overcome only by long periods of low caloric intake. 7. We have no cure for diabetes; but we have a greatly improved method of treatment, particularly as regards prolongation of life and the avoidance of surgical complications, as many observers who have employed the general principles of treatment advanced by Allen will testify.

Remarks on the Dangers Arising from Their Impaction and Some Difficulties Which May Be Met With in Their Removal; a Plea for the Abolition of the Coin Catcher, the Blind Use of the Bougie and Probang, and Their Replacement by the Direct Endoscope Methods of Extraction. Irwin Moore.

1. **The Differentiation of Mankind into Racial Types.**—Arthur Keith, in his presidential address delivered before the Anthropological Section of the British Association for the Advancement of Science, reviews the ancient and modern theories to account for different racial types and propounds his theory whereby he attributes such differences to the endocrine glands. He discusses the endocrine glands as growth controlling structures and the mechanism of the control of growth, and states that the sporadic manifestation of Mongoloid characters in diseased children and in healthy adult Europeans, the generic characters which separate one kind of ape from another, the bodily and mental features which mark the various races of mankind are best explained by the theory that the conformation of man and ape and of every vertebrate animal is determined by a common growth-controlling mechanism which is resident in a system of small but complex glandular organs, the pituitary, pineal, thyroid, suprarenal and interstitial glands. The pituitary gland is concerned with the production of acromegaly, gigantism, and disordered growth in which the length of the limbs is increased disproportionately and where a eunuchoid condition of the body develops. There must be a condition of the opposite kind where the functions of the pituitary are disordered and reduced. Dwarfism may also result from a failure of the thyroid gland. On the evidence at our disposal—evidence that is being rapidly augmented—we are justified in regarding the pituitary gland as one of the principal pinions in the machinery which regulates the growth of the human body and is directly concerned in determining stature, cast of features, texture of skin, and character of hair—all of them marks of race. When we compare the chief types of humanity, the Negro, the Mongol, and the Caucasian, we can recognize in the last named a greater predominance of the pituitary than in the other two. The sharp and pronounced nasalization of the face, the tendency to strong eyebrow ridges, the prominent chin, the tendency to bulk of body and height of stature in the majority of Europeans, are best explained, so far as the present state of our knowledge goes, in terms of pituitary function. He also shows that local growth—the development of a particular trait or feature—is dependent both on the hormones supplied to that part and also to the condition of the receptive mechanism of the part. In this way a local derangement of growth as an acromegaly or gigantism confined to a finger or eyebrow ridge, to the nose, to one side of the face, could be explained. It was by a variation in the sensitiveness of the local recipient that one might explain the endless variety to be found in the relative development of racial and individual features. The rational interpretation of acromegaly is that it is a pathological disorder of the mechanism of adaptational response; in the healthy body the pituitary is throwing into the circulation just a sufficiency of a growth regulating substance to sensitize muscles, bones, and other structures to give a normal response to the burden thrown on the body. But in acromegaly the body is so flooded with the substance that its tissues become hypersensitive and respond by overgrowth to efforts and movements of the slightest degree. It is not too much to expect, when we see how the body and features become transformed at the onset of acromegaly, that a fuller knowledge of these growth mechanisms will give us the clue to a race differentiation. The part played in growth mechanism by the other endocrine glands is likewise discussed.

2. An Experimental Investigation of Certain Materials Used for Nerve Suture. Percy Sargent and J. E. Greenfield.
3. Combined Sclerosis with Heterotopia of the Spinal Cord. George E. Bennie and Oliver Latham.
4. Diaphragmatic Hernia of the Entire Stomach and Great Omentum. Grant Andrew.

1. **The Epidemiological Point of View.**—Major Greenwood says that the epidemiologist is an observer from the mountain top, concerned with disease as a mass phenomena; his business is not with individuals, but with aggregates. He seeks to define the relations of these aggregates, the general arrangement of the streets in the cities of the plain, but is not concerned with details. This was the Hippocratic point of view once adopted by all physicians and some have accordingly argued that it is the duty of the epidemiologist to take Hippocrates as his guide. There are objections to this theory. If Hippocrates had had a modern equipment he might still have preferred the method he actually adopted; but he might not have done so; he had no choice. The writer does not think that a detailed examination of the epidemiological teaching before the days of Sydenham a suitable introduction to the subject to-day. Sydenham, however, contributed to both the practice and the theory of epidemiology, and from his time dates the development of the two scientific methods—that of statistics and that of clinical field observation, though they were not co-ordinated for generations. Farr and Sinom were the greatest exponents of the statistical and field methods which must be employed by an epidemiologist. These men were not mere highly expert technicians; they knew that the mountain top observer could not rely upon the telescope alone or upon the camera alone. Farr did not think that epidemiology was but a branch of mathematics. Simon

did not look upon it as a mere blend of unsystematic botany and history. They fully realized that the song was of the man as well as of the arms; that the conditions of human life—both, as we now say, environmental and eugenic—were quite as important to the epidemiologist as the *materies morbi*. Although since the days of Farr and Simon the technical methods at the disposal of the epidemiologist have been greatly improved, there has not been a corresponding improvement in the general quality of epidemiological work. There are two reasons for this. Those in official positions giving scope for epidemiological work have been increasingly burdened with administrative duties and less unfettered in their choice of subjects; the private investigator has either been enamoured of the pure technic, more interested in the fashioning of tools than in the shaping of material, or has been tempted to abandon epidemiology for the dazzling prospects of research in bacteriology or pathology. The result is that while some epidemiological work is tendencious, some exclusively mathematical, some a mere padding of bacteriological papers, hardly any can bear comparison not merely with Farr's or Simon's but with that of their pupils. The science of medicine cannot be developed harmoniously if the epidemiological point of view is neglected; there is still much to be learned that only the epidemiological method can teach.

3. Increasing Prevalence of Scorbutus. J. Don Miller.
4. Further Observations in the Use of Calcium Chloride in the Treatment of Tuberculosis. Thomas J. Beasley.
5. Series of Bedside Clinics at Indianapolis City Hospital Under Service of Dr. S. E. Earp.
6. Advantages of Conferences of Physicians, Pharmacists and Dentists. Leo Dorn.
7. Therapy of Early Indianapolis. Winfield Scott Lynn.

1. Acute Intestinal Obstruction and Danger from Morphine and Delay.—Murray Nathan Hadley states that he has reason to believe that the practice of giving repeated doses of morphine in grave abdominal crises is in no sense obsolete. He concedes that no one will deny the urgent need and absolute necessity of the first ¼ grain hypodermic of morphine and possibly the second in these cases. But before the second dose is administered the surgeon should be consulted and a definite surgical plan for the relief of the intestinal obstruction should be decided upon. Conservatism must be practised if the acutely obstructed cases are to be saved, that is the cases that have gone beyond the period in which operative procedures of any magnitude can be safely undertaken. There is only one thing that can be safely done and that is under local anesthesia, an enterostomy for relief of the obstruction, leaving the pathology to be attended to later. If a general anesthetic is given and a search should be made through a wide incision for the cause of the obstruction, and then an attempt made to resect, the patient will surely die. Experimentation has shown conclusively that the cause of death in acute intestinal obstruction is always the effect of toxins within the gut. The deduction from this is that toxic material must be eliminated from the gut above the point of obstruction. Several cases are cited which illustrate the dire consequences of delay in bowel obstruction, that delay still exists among the class of patients usually referred to the City Hospital, and that there is room for improvement in the surgical judgment in the handling of these cases.

1. Some Medicaments Used Lang Syne. Douglas W. Montgomery.
2. The Surgical Treatment of Oblique and Direct Inguinal Herniae in the Male. Based Upon the Causative Anatomic Factors. H. K. Bonn.
3. Overfed Babies. W. D. Hoskins.
4. The Relation of Infected Tonsils to the Thyroid Enlargement in Adolescence. James C. Carter.
5. Physical, Mental and Moral Keep-Wells. Mrs. Arthur MacDonald.
6. Religious Biology. J. W. Birchfield.

Overfed Babies.—W. D. Hoskins attributes most of the gastrointestinal disturbances of infants to overfeeding. This overfeeding in milk-fed babies, he says, is usually due to an excess of fat, too much food at a time, or too frequent feeding. If nature is kind the child developes vomiting or diarrhea and the excess is carried away and no serious damage may ensue. If the over-feeding is apparently well tolerated, and the digestive tract sounds no alarm, the more delicate functions and processes of nutrition are damaged, this damage being sometimes manifested as a marked overgrowth, the well-known fat prize baby. In other cases again the over-feeding may result in stationary weight, until the most extreme degree of emaciation is produced, or, again, the overfed baby may be suddenly attacked with convulsions or profound coma. These cases are usually fatal. Such explosions may occur at any time but are more frequent in hot weather. Infant feeding is no longer a hot weather specialty. The battle with and for these difficult feeding cases is on every day in the year. Most difficult feeding cases are due to over-feeding. It is scientific folly and a waste of time to try one food after another in the hope that the new one will hit. The only rational treatment is to withhold for a time the offending food elements, then gradually and carefully to reintroduce small percentages of these until tolerance has been restored. Drugs have little or no place in the treatment of these cases. The baby that must have castor oil once or twice a week to keep it from getting sick is badly fed.

4. The Relation of Infected Tonsils to Thyroid Enlargement in Adolescence.—James C. Carter states that it has been the observation of many clinicians that some girls during adolescence show a slight to a marked enlargement of the thyroid gland, usually bilateral. This condition he believes to be one of hypothyroidism. He also observes that the hypothyroidism that comes with a chronic infection of the tonsils manifests itself by an enlargement of the thyroid gland. He notes, furthermore, that sudden enlargement of the thyroid gland frequently follows an attack of acute tonsillitis. In the pediatric clinic with which he is associated it has been their practice in girls with enlargement of the thyroid gland to remove the tonsils, and a number of cases are cited which show a reduction in the size of the thyroid gland following removal of the tonsils. It would seem that the toxins produced in the tonsils caused the increase in the first place. The growth took place to supply the demand for more of the thyroid secretion. The giving of thyroid extract in small doses after the initial reduction in size seems to aid in a still further decrease. The giving of thyroid extract alone will in time cause some reduction in the size of the thyroid, but the tonsils must come out if this reduction is to be permanent.

Length of the Embryo.—Sombret, apropos of the fluctuations in the dimensions and weights of the fetus and placenta at different ages, announces a notable exception. At the close of the third month the fetal length is almost constant, so that if we add 5 cm. per month for the next three months we shall have the age of the fetus or duration of gestation to within a fortnight. Between the third and fourth months the weights of the fetus and placenta agree.—*Journal de médecine et de chirurgie pratiques.*

Warm Applications in Stomach Ills.—Lüdin refers to the occasional use of these remedies in gastralgia, gastric ulcer, etc., in the form of cataplasms. The undoubted benefit may, of course, be attributed to the incidental rest, to suggestive influence, etc., rather than to the physiological action of heat. The author has proven by experiments on fistula dogs that warm applications raise the stomach temperature, while diathermy exerts the same effect. Experience with human patients shows that the secretory action of the stomach is not modified. Under *x*-ray control warmth is seen to promote gastric peristalsis and hasten the evacuation of the chyme. In practice the cataplasms relieve gastralgia and the pain of gastric ulcer and apparently hasten the healing process, and are also valuable in patients with gastric stasis.—*Correspondenz-Blatt für Schweizer Aerzte.*

Book Reviews.

Training School Methods for Institutional Nurses. By Charlotte A. Aikens, formerly Director of Sibley Memorial Hospital, Washington, D. C.; formerly Superintendent of Iowa Methodist Hospital, Des Moines, and of Columbia Hospital, Pittsburgh; author of "Hospital Management," "Studies in Ethics for Nurses," etc. Philadelphia and London: W. B. Saunders Company, 1919.

The first part of this book deals with the training of pupil nurses. The author discusses various phases and problems of this subject, and rightly reminds the nurses that the educational features of their training are not the whole of proper training; but that common sense, human sympathy, general intelligence, and moral character and refinement are equally requisite. Pupils, the probation period, teachers, and methods of study all receive attention at the hands of the author, and the chapters dealing with these topics are healthy and serviceable.

The second half of the book deals with the head nurse, and discusses her relation to patients and to probationers and junior nurses; it also contains much sound advice on the subject of bedside teaching and general management and housekeeping. The book should prove equally useful to nurses who hope to become head nurses, to head nurses themselves, and to those who have the appointment of head nurses. The author of this book is well known as a successful writer on nursing topics, and the present volume will add to her reputation.

The International Medical Annual. A Year-book of Treatment, and Practitioner's Index. By various contributors. 1919. Thirty-seventh year. New York: William Wood and Company.

This is an unusually complete résumé of much of the recent work in medicine and surgery. In almost every article can be seen the results of the newer methods and procedure necessitated by the war. In many instances there are conflicting views; these are given and discussed. A work of this kind is an absolute necessity to every practitioner; some readers prefer a monthly volume, some a quarterly, and some an annual. For this last class there can be nothing better than the present volume.

Hygiene and Public Health. By George M. Price, M.D. Author of "A Handbook on Sanitation," "Tenement-House Inspection," "Hygiene and Sanitation for Nurses." "The Modern Factory," "Director, Joint Board of Sanitary Control. Second edition, thoroughly revised. Philadelphia and New York: Lea & Febiger, 1919.

The new edition of this epitome contains a few changes, the most important being the inclusion of some forty pages on the control of communicable diseases, and the omission of the chapter on sanitary inspection. Hygiene is a large subject and embraces so many correlated branches and sciences that an epitome on the subject is particularly necessary for the student. This is one of the most useful volumes of a well known series.

The Pituitary. A study of the morphology, physiology, pathology, and surgical treatment of the pituitary, together with an account of the therapeutical uses of the extracts made from this organ. By Blair Bell. New York: William Wood & Company, 1919.

The subtitle of this monograph accurately describes its contents. The reader will find here the most complete summary of our present knowledge with regard to the pituitary body. Much of the volume is founded on the author's own experiments and researches; at the same time, the labors and writings of others are represented and, where possible, correlated. A good working bibliography is also appended. The book is well arranged, is very readable, and is most lavishly illustrated. The author gives very necessary warning in connection with the so-called "literature" issued by drug houses which have preparations of pituitary (and other) extracts for sale. He says: "These accounts are often intentionally inaccurate, in that the literature quoted refers only to work done with the preparations made by the firms concerned. In this way credit has been wrongly given to, and assumed by, continental clinicians for what was discovered and described in this country at least a year before the first continental paper appeared; and, unfortunately, some medical writers appear to obtain their historical information from these pamphlets, rather than from the scientific literature on the subject." In spite of its size the present volume will form a most welcome addition to the working library of any up-to-date physician.

Anatomical Diagrams for the use of Art Students. Arranged with analytical notes and drawn out by James M. Dunlop, A. R. C. A., Antique and Life Class Master and Lecturer on Artistic Anatomy in the Glasgow School of Art. With introductory preface by John Cleland, M.D., LL.D., F.R.S., Professor of Anatomy in the University of Glasgow. Fourth edition. New York: The Macmillan Company, 1919.

This is a small quarto volume of seventy-two pages, and contains such points of surface anatomy as are of interest to art students. The subcutaneous prominences of the bones, and the insertions and lines of attachment of the muscles are clearly indicated; and the general arrangement of the work is admirably adapted to the needs of students. As a rule, one diagram shows the bones of some selected part of the body, and facing this is another diagram showing the superficial muscles of the same region. There is no descriptive text, but the author appeals to the eye of the reader instead of giving a lengthy statement of the situation, direction, and other details of the bones and muscles.

Experiences in Surgery With the Second Division of the American Expeditionary Force. By Burton James Lee, Lieutenant Colonel, Medical Corps, U. S. A. The Society of the New York Hospital General Bulletin, Vol. I, No. 12, July 1, 1919.

The title of this brochure is something of a misnomer, for it covers experiences of a surgeon rather than experiences in surgery. There is a very interesting account of Lt. Col. Lee's trip to France, and observations regarding conditions and events in connection with his subsequent wanderings over France and Belgium occasioned by his assignments to duty in various places and in various capacities; his attempts to get suitable hospital buildings and sites in and near various parts of the battle zone and sufficient personnel and equipment after getting hospital quarters; an appreciation of the courage and grit of the American soldier; and praise for various men of the medical sections of our own and allied armies with whom he came into contact. There is practically nothing of value regarding methods of operating or wound treatment, types of cases handled or results; but as a recital of the experiences of a *surgeon* the article is very interesting. There is an introduction by Lt. Col. Brewer giving an appreciation of Lee's work which we are sure is well merited.

Geriatrics. A Treatise on Senile Conditions, Diseases of Advanced Life, and Care of the Aged. By Malford W. Thewlis, M.D., Associate Editor, Medical Review of Reviews. With Introductions by A. Jacobi, M.D., LL.D., and I. L. Nascher, M.D. St. Louis: C. V. Mosby Company, 1919.

The study of conditions peculiar to advanced life and the problems met with in the care of the aged constitute no new branch of medicine but one that is curiously neglected in most curricula. Since old age must be classed among the incurable diseases the majority are inclined to waive it impatiently aside and say, "Nothing can be done." The author is one of a few who have protested the inhumanity of such a stand and presents this work as an aid in the treatment of these conditions. He is a pupil of Nascher whose textbook on geriatrics was the first to appear in English. He presents his subject through the medium of case-reports followed by a discussion of the problem illustrated. The matter is considered sympathetically and with a broad common sense that is attractive.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-ninth Annual Session, Held at Harrisburg, Sept. 22-25, 1919.

First Day—Tuesday, September 23.

THE RETIRING PRESIDENT, DR. FREDERICK L. VAN SICKLE, IN THE CHAIR.

President's Address.—Dr. CYRUS L. STEVENS of Athens in his Presidential Address said that a review of the "Transactions" showed that each year the State Society had urged some measure, the adoption of which would have been helpful to the community and in some cases detrimental to the income of the practising physician. The system of medical education in the State was regarded as second to none in the world. Attention was called to the outstanding defect in the treatment of the insane in that institutional care was not sufficiently early insisted upon. While the improvement in the sanitation of workshops was marked much of such work remained to be done in homes. With the removal of the curse of alcohol from the presence of the workingman and from politics, the difficulties attendant upon proper housing should be more easily overcome. Reference was made to the fact that there had been a smaller proportion of venereal disease in the United States Army during the late war than in any large army in history. In Dr. Stevens' opinion the action of Secretaries Baker and Daniels in supporting the Navy and Army medical officers to whom such improvement was due, should count much in counterbalancing the mistakes made in their departments. That compulsory health insurance was a live issue was shown by the fact that in eight States commissions had been appointed to study the question. If such health insurance was found desirable the profession must advocate it and help shape its provisions in such way that it might be most helpful to the people and least harmful to the physicians.

Community Sanitation as Based Upon the Knowledge of Camp Sanitation.—Dr. WILLIAM G. TURNBULL of Cresson said that to secure for the communities the results obtained in camp sanitation there must be centralization of authority, sanitary officers trained by the central authority, to which body they must be responsible; the employment of only licensed health officers for communities to be permitted with salary sufficient to attract capable men. Of such salary a pro rata share should be borne by the central authority. There should be also a health education campaign.

The Work of the Sanitary Engineer in the Pennsylvania Department of Health.—Mr. C. A. EMERSON, Jr., Chief of the Engineering Division, indicated the potential service of the Division to the medical profession and pointed out the necessity of co-operation between the two organizations in securing ultimate results. The work of the sanitary engineer was outlined as comprehending water supply, sewerage, waste disposal, milk supply, and housing. Of these the provision of a pure water supply constituted the most important item. There were throughout Pennsylvania 136 filter plants supplying pure water to over 4,000,000 people. Reports of the daily operations of the water purification plants were required by the Engineering Division. The marked need in all municipalities of better housing conditions was referred to. Efficiency of sanitation was said to be measured by the decrease in typhoid rate. Pennsylvania's death rate from typhoid had dropped since 1906 from 54.8 per 100,000 to 10.1, a reduction of 81 per cent.

Dr. EDWARD MARTIN, State Commissioner of Health, supplemented the offer of aid made by the Governor and representatives of the Health Department to the medical profession and asked for the co-operation of the profession in matters of the health of the people.

Dr. FREDERICK C. MONKS of Kittanning suggested that all questions of sanitation might be reached by the State through the trained county medical inspector, and thought it ought to be possible to call upon the county health officer to remove a nuisance which the municipal health authority had failed to abate.

Roentgen Ray as an Aid to Diagnosis of Chest Conditions.—Drs. CLARENCE R. PHILLIPS and ALLEN Z. RITZMAN of Harrisburg presented a comparison of the findings by usual methods of physical examination and those of the *x*-ray. The importance of a knowledge of the history of the case, of the anatomy and pathology of the lungs and heart and of the ability to interpret the *x*-ray plate was urged in diagnosis. The importance of a knowledge of the history was emphasized in a case in which a child was aspirated for fluid in the chest and in which the history showed operation for sarcoma of the testicle.

Dr. THOMAS KLEIN of Philadelphia regarded as unfortunate the fact that there was no clinical symptom at all times pathognomonic of tuberculosis. It was therefore highly essential that in addition to the clinical findings and the *x*-ray the history of the case be given careful consideration. In determining the state of activity in pulmonary tuberculosis this clinical history was the most important factor. He regarded no condition in medicine so difficult to diagnose as that of tuberculosis in an asthmatic. Only by the evidence of the positive sputum should a case of asthma be diagnosed tuberculosis.

Impressions Resulting from Experience in the Pennsylvania Legislative Session of 1919.—Dr. FREDERICK L. VAN SICKLE of Olyphant pointed out the need of a strong organization of the medical profession which should have an influence upon constructive legislation. He regarded as desirable that the pulse of the medical profession be noted prior to the passage of certain acts relative to the department of health, and of education that their application with less friction be possible. Attention was urged upon the matter of health insurance upon which in two years the Commission on Health Survey would make another report. Concerning legislation in medical matters Dr. Van Sickle believed the profession should maintain a publicity bureau which should furnish to the press accredited items.

Second Day—Wednesday, September 24.

DR. JULIUS COMROE OF YORK, THIRD VICE-PRESIDENT, IN THE CHAIR.

Physical Findings of Pennsylvania Men in the Draft.—Major W. G. MURDOCK, State Draft Executive for the United States Army, Harrisburg, read this paper in which he stated that much had been written and said, and to his mind a great deal of it erroneously, about the high percentage of rejections not only by examining physicians of draft boards, but also by medical officers at camps of men who had been passed as physically qualified by board physicians. The first report of the Provost Marshal General showed the ratio of rejections for the State of Pennsylvania to be 46.67 per cent., the highest of any state in the Union. If these figures had been correct there surely would have been cause for alarm, but fortunately they are not. In the same report statistics were given showing the number of men accepted and rejected in detail by every local Board in the State, and a tabulation of these figures showed that during this period the percentage of rejections had been only 28.55 which was less than the average for the entire country. Statistics showed that the physical condition of the men of this State, in spite of the thousands of accidents annually in the industrial plants, was not alarming, but it could undoubtedly be greatly improved by a proper system of health education. In many cases of rejection the registrant had not been aware of any physical defect. The record made by 2000 physicians in this State in the examination of registrants was unimpeachable. The physical condition of the men of the state was not nearly so bad as one might be led to believe from many newspaper and magazine articles, but it could and should be bettered as far as possible and the best way to accomplish this was by a system of universal training and schooling for a period of 3 months for 18-year old men, based, not on the idea of building up a fighting machine, which had already doomed the present bills before Congress, but with the sole idea of improving the health of the individual, pointing out his

defects and teaching him how to take care of them. For, after all, in case of emergency, the general health of the men, not a short period of instruction in military tactics, would determine the strength of an army.

Dr. FREDERICK L. VAN SICKLE of Olyphant said that he believed that Pennsylvania might have had a larger number of rejections than some other States because of her industries. Pennsylvania had had the opportunity for many years to cripple its workers in mines, in mills, and in manufacturing plants. It had been the reports of the high rejection of the State of Pennsylvania by our medical men which caused the request of this paper. It seemed to him that we should have endeavored to correct these reports when some papers had as high as 43 per cent. of rejections in the State of Pennsylvania and he was glad that Major Murdock had placed on record 28.55 per cent. and only 8 per cent. of men rejected in our camps.

Colonel EDWARD MARTIN of Philadelphia, Commissioner of Health of Pennsylvania, said that this paper was a vindication of the profession at large and particularly the profession of Pennsylvania. Through Dr. Finegan, the head of our Public School System, there would be introduced into every public school of this state a curriculum which involved not only a thorough systematic education in health, that course ranking with mathematics, the students and teachers being graded on it and being promoted on it, but also a regular systematic course in physical training.

Dr. C. A. E. CODMAN of Philadelphia said that during the course of training at Fort Sill they had a number sent to the Base Hospital for obvious defects. Among the number were those said to be suffering from valvular heart disease. After careful examination it was found that many of these men had a simple mitral lesion. If some statistics published by the British were recalled it would be found that their cardiovascular commission decided that a mitral murmur was almost physiological in adolescents and was of comparatively no significance. Working upon that basis, a great many of these men had been returned to duty.

Col. WILLIAM J. CROOKSTON of Pittsburgh said that he had been surgeon to the Twenty-eighth Division in Camp Hancock, and he believed in that time perhaps 1500 to 2000 men with mental defects and physical defects were turned down. They had a tuberculosis man, a heart specialist, and a psychiatrist, and they turned men down right and left, and no man went abroad who was determined by these boards to be defective. Every alcoholic was turned down, 200 of them. He believed the Twenty-eighth Division was as nearly perfect, physically and mentally, as any division that ever went abroad.

Major W. G. MURDOCK of Harrisburg said that he wanted to bring out forcibly two things: (1) That the physical condition of the men of Pennsylvania was not as bad as it had been represented, and (2) that the work of the examining physicians of the state could not be criticized. He knew from his experience and correspondence with other states during this period that they were not up to the standard that the Pennsylvania men set, and he did not think that any physician, and there were more than 2000 of them, engaged in this work in this state, needed to be ashamed of any of the work that he had done.

What the Medical Reserve Corps of the Army Should Be.—Surgeon General M. W. Ireland, U.S.A., prepared this paper, which was read in his absence by Colonel EDWARD MARTIN, who said that the creation of the Reserve Corps was decidedly an act of foresight, for had it not been for the provisions of this act the country would not have been able to assemble as a cohesive organization the large number of eminent men who so promptly responded to the call of their country on that eventful day upon which the United States entered the world war. After the declaration of war on April 6, 1917, the first American unit to arrive in France was a Red Cross Military Hospital staffed almost entirely by men who were officers in the Reserve Corps, and this event enabled the medical profession of the United States to point with pride to the fact that a medical unit, the personnel of which was almost entirely from civil sources, was the first one in the army to enter the zone of conflict. Many of these gallant officers had made the supreme sacrifice and rested with the noble dead in France and Flanders, reposing beside those with whom they had lived, with and to whom they had ministered in the great offensive that finally brought the enemy to his knees. Lest these should have made their sacrifice in vain it behooved us to do all that was within our power to affiliate ourselves with the military machine of this country, and in every way to improve the living conditions of the populace, to the end that the physical standard of the militarily trained American youth might be such that no nation would have the temerity ever again to seek an issue on the field of battle with the United States. The comparative success of the Medical Department of the American Expeditionary Forces must not be taken as a standard of sufficiency of personnel, equipment, or transportation, for it might be a surprise to learn that the Medical Department of the combat army of the Expeditionary Forces had only two-thirds of the personnel, one-fourth of the evacuation hospitals, and one-third of the transportation allowed by existing tables of organization.

Col. REUBEN MILLER of Washington, D. C., said that the Medical Reserve Corps had given much to the country, but it was found to be always true that those who had given most were the easiest to approach when more was wanted. The war was over and it was right that most of those who had been in service should turn their attention to civil pursuits and forget in a measure the military work that they had been engaged in, but they should not forget that this war might not be the last war. We did not know when war would come again. The appointments in the Medical Reserve Corps were now limited to those who had had service in the present war, who had served honorably, and had requested appointment in the reserve subsequent to discharge from the service. That condition of things could not go on. No organization, no matter how high grade its personnel, could live and thrive without the constant introduction of new blood. The youngest of those now in service would not remain young indefinitely. We must have new blood. The source from which we ought to obtain that new blood was the recent graduates from the medical schools, but he thought these graduates should, preliminary to graduation, be given instruction in medicomilitary matters. Although the law did not limit the organization, the War Department intended to limit the development of these organizations to Class A Medical Schools, because the department had not an unlimited supply of instructors. He would be very glad indeed if this society saw its way clear to adopt a resolution favoring the introduction into the curriculum of the medical colleges of the State of Pennsylvania of the requirements of the National Defence Act of the Reserve Officers' Training Corps unit. He thought this society would have a great deal of influence with the colleges and it was very fitting that Pennsylvania should take up seriously the matter of educating for any possible demands which the public might make on them.

Dr. C. A. E. CODMAN of Philadelphia said it was the duty of every man who had had the privilege of serving in the great war to volunteer as a member of the Medical Officers' Reserve Corps for the reason that he had been trained and efficiently so. The value of trained men was self-evident, and if we could start the Medical Officers' Reserve Corps with men who had been in the army we would make a great step in advance. We would need the younger men to come on and take the place of the men who would pass on. These men should regularly attend schools and they should be taught the modus operandi of field hospital work and evacuation hospital work. Men should be taught the paper work which was extremely difficult and irksome, but nevertheless it must be done in order that the reports might be complete. In addition to that, men should be trained as executives, medical men should be trained how to organize hospitals and how to take care of men when once put in command of organizations of that kind. Another point the War Department should take up was the revision of the medical manual. Every man who had worked with that manual knew its weaknesses and it was time that antiquated manual should be revised and brought up to date.

Pennsylvania's Campaign Against Venereal Disease.—Dr. S. Leon Gans of Philadelphia read this paper, saying that the prevalence and seriousness of venereal disease had been sufficiently established to both the professional and lay mind to demand an energetic campaign for the minimizing of this class of infection. Now the important problem was the angle of attack. The State Department of Health had thoughtfully outlined a sane program and the success or failure of this campaign would depend quite as much upon the physician individually as upon any work that this division might undertake. The health of the commonwealth was in the hands of the medical profession, of which the department was one unit. The State Department of Health consistently considered the viewpoint and the cooperation of the medical profession in any of its plans, and without their cooperation the division did not expect to "put it over." This was the day of preventative medicine, therefore, (1) all means must be utilized to prevent infection; (2) methods must be employed to locate and detect infected persons; (3) when infection was detected, treatment must be carried out until a cure was accomplished. Under prevention was classed the educational campaign consisting of organizations which were being formed in every town in the state. These organizations would be composed of responsible men and women, their purpose being to carry education to the individual in his or her town. The block system had been successfully carried out, which brought comprehensive education into each home and dealt with broad public health work. These organizations would supervise a system of talks to assemblies of men and women which would be graded as to sex and age, and followed by the distribution of carefully prepared pamphlets. It was recommended that a selected course in sex instruction be introduced into schools and that the parents, the clergy, and the family doctor be urged to discuss this problem so that the growing child would have a sane sexual education rather than a morbid sensual smattering. All inmates of penal institutions or reformatories were being examined and treated when infected. They would be given instructions concerning prophylactic measures and the dangers of infection and the spread of venereal disease. Framed posters would be distributed throughout the state giving information on venereal infection, and advising the proper method of securing relief, also a warning against quacks. The principle of the old fumigation method was now being tested.

Col. Edward Martin of Philadelphia said that because the time for talking was over and the time for doing was here he was going to ask his colleagues to adopt a resolution which he would read and which was direct and clear, and which would really help: *Resolved*, That the Medical Society of the State of Pennsylvania favor a rational campaign against the incidence of venereal diseases—By the elimination of the prostitute, utilizing social agencies for making her self-supporting by a less pernicious occupation; by the general knowledge and reasonable availability of the immediate treatment package; by the discovery and treatment till cured of foci of infection; by the distraint of those infected who by occupation, temperament, or habits endanger others. Be it further *Resolved*, That the United States Government through the Treasury Department, Public Health Service, be requested to give to Philadelphia, our port of entry, that protection against a steady influx of fresh venereal infection through the merchant marine, which it now affords against other transmissible and quarantinable diseases. (The resolution was adopted by the general meeting.)

Dr. Robert L. Schaeffer of Allentown said that mercury had been for years the drug to kill the spirochete. Salvarsan a few years ago came into vogue and made such rapid progress that he believed some of us neglected the mercurial treatment. This he thought was a mistake. If we treated our cases with salvarsan or arsenical preparations we would not cure them. We would have to combine our treatment with mercury. He had had experience with the inhalation treatment in twelve or fifteen cases. He had found the clinical symptoms in these cases to rapidly disappear. The majority of these cases become slightly salivated.

Dr. M. A. Neufeld of Chester said that to anyone who tried it the simplicity of its use appealed first of all. After you had made the diagnosis and examined the patient carefully you could leave that patient to your nurse. You could go ahead and do other work. You did not have to cut down on a vein.

Col. Edward Martin of Philadelphia said that with same little personal experience of syphilis and some little acquaintance with its literature, this was the first time he had heard salivation advocated. He regarded salivation as a lowering of vital resistance. A man got well by his own vital resistance. Each time a patient was salivated his symptoms might disappear, as they would if he were not salivated; they would disappear merely and his cure would be postponed. As an expression of personal opinion he would say that salivation, even in the faintest degree, was the one thing to be avoided.

The Antinarcotic Law.—Dr. Thomas S. Blair of Harrisburg, chief of the Bureau of Drug Control, presented this subject, saying that the Federal and the state antinarcotic law required as regards physicians that they use narcotic drugs according to the data set out in extended textbooks on materia medica, therapeutics, and practice of medicine. This did not exact anything more; except that the physician render certain reports and that he do what he can to help these poor people who were addicted to drugs. They were getting more and more an exact map of the narcotic conditions in the state, and it showed that pro rata annually every doctor in the state must be credited with a little more than 2 ounces prescribed in his practice either in dispensing or prescriptions to patients; about 5 drachms of cocaine and 6 ounces of opium. One-third of the physicians of this state, the less intelligent ones, were responsible for giving out 90 per cent. of this total quantity of narcotic drug. So then the rates were from almost nothing for some men up to the vicious violators of the law as high as 40 pounds of opium in a year. Morphine has ranked as high as 14 pounds in case of one alleged doctor.

Third Day—Thursday, September 25.

Pneumonia and Empyema: Symptomatology and Diagnosis.—Dr. Thomas G. Simonton of Pittsburgh read this paper. He drew attention to the nerves in relation to the lung and to their position in the mediastinum, and to the fact that in a beginning pneumonia or septic peritonitis, with irritation of the phrenic nerve, pain might be referred to the tip of the acromion; this by reason of the fact that the phrenic, the fourth cervical nerve, sent communicating branches to the brachial plexus, which in turn supplied cutaneous branches to the tip of the acromion. In several cases of pneumonia which he had seen the pain was most severe at this point before a diagnosis of pneumonia was made or suspected. It was stated that autopsies upon patients dying of influenza complicated with pneumonia showed a mediastinitis, peribronchial inflammation, tracheitis, free fluid in the mediastinum, pulmonary infarcts, enlarged lymph glands, and gangrene of the lungs. Symptoms of hoarseness, croupy cough, partial or complete aphonia, and inspiratory dyspnea, observed in pneumonia during the influenza epidemic, were attributed to the fact that the free fluid, or swollen glands in the mediastinum, or the peribronchial inflammation caused a recurrent laryngeal or vagus paralysis.

The Management of Pneumonia, Its Complications and Sequelæ.—Dr. Lawrence Litchfield of Pittsburgh said that pleuritic exudate should be drained only after aspiration was found to be insufficient. Rib resection was then not advisable. Follow-up treatment should be carried out with Carrel-Dakin washing and calorie feeding. Maintenance of the water supply to the body by intravenous injection of dextrose solution was important if other means were inadequate. Attention was called to the efficacy of atropine in beginning pulmonary edema (gr. 1/50), to the danger of feeding during the first days of the attack, and to the routine use of opiates. The author had seen death follow double pneumothorax from exploratory aspiration or exploratory needling; also embarrassment of circulation and respiration by a unilateral pneumothorax. Alarming distention of the abdomen due to gastric

dilatation might be promptly relieved by the stomach tube. For distention in the intestines pituitrin hypodermically was regarded as a valuable adjunct to the usual enemas. By the free use of caffeine and epinephrin an almost exhausted organism might be tided over a dangerous point. During an epidemic he regarded Col. Dunham's nasopnaryngeal disinfection as more dependable than vaccines as thus far established. Dr. Simonton's keenest regrets in the autopsy room had been due to undiagnosed complications of pneumonia.

Surgical Complications of Pneumonia and Empyema.—Dr. Evan W. Meredith of Pittsburgh said that empyema was by far the most frequent complication of pneumonia, having occurred in several of the base hospitals in from 7 to 15 per cent. of all types of pneumonia. Pneumonia, secondary to measles, and streptococcic bronchopneumonia, had given the largest percentage. In autopsied cases dying of bronchopneumonia a rather high percentage showed involvement of the peritoneum. Suppurative perichondritis of the thyroid cartilage had been observed in three patients; abscesses in the abdominal wall in the suprapubic region were seen in two patients. Arthritis with effusion was a frequent complication. While in pneumococcic empyema the prompt removal of pus was regarded as sound practice, in streptococcic empyema removal of the exudate by open incision was decidedly contraindicated. Local anesthesia with novocain, ½ to 2½ per cent., was the method of choice in a large percentage of cases. In children the author used ether exclusively.

Acute Alveolar and Interstitial Emphysema in Influenzal Bronchopneumonia.—Dr. Frank F. D. Reckord of Harrisburg presented data in connection with the epidemic influenza at Camp Devens. Of approximately 45,000 men, 14,000 required hospital treatment. Of these 2500 developed pneumonia, with a mortality of 800, or 32 per cent. It was evident that death from influenza meant death from lung complications. Two strikingly characteristic types of lungs were observed in the cases studied, one where death occurred soon after onset of pulmonary signs, and the other in patients living ten or more days after onset. Bronchiectasis and interstitial emphysema were of rapid development. The gross appearance of the lungs was markedly different in various localities; this was true also of the bacteriology. A striking type of reaction observed was a condition of acute alveolar emphysema with a deposit of a hyaline fibrinous material on the alveolar walls. This was the one distinctive feature in the pathology of influenza pneumonias and its constant occurrence was regarded as indicative of the entity of the initial lung infection. The character of the hyalin fibrin deposit around air vesicles and upon the alveolar walls suggested a pouring of exudate into the alveoli from the bronchioles and alveolar ducts at a time when air was able to pass. Thus the patient was virtually blowing bubbles in his own lungs, into a medium of exudation relatively poor in fibrin. The organism occurring with greatest constancy was the influenza bacillus. While lack of knowledge of the pathogenicity of the influenza bacilli and failure to produce the disease with pure cultures formed a strong argument against its being the cause of influenza, to explain the constant occurrence of the influenza bacilli in a series such as studied was difficult. The occurrence of the bacilli influenzae in pure cultures in the early stages was believed to firmly establish the existence of a bacilli influenzae pneumonia. The author's indebtedness to Dr. S. Burt Wolbach of the Harvard Medical School was acknowledged for use of slides and for assistance in connection with the paper.

Dr. George R. Moffitt of Harrisburg stated that in a number of cases of measles and pneumonia autopsied there was not found the extensive bronchopneumonia which had been described. In many cases in which death had been sudden there were found from 2 to 3 liters of seropurulent fluid in the pleural cavity, with thick plastic exudate filling the lungs. That this could not be withdrawn by pipettes explained failure to discover it before death. Hemolytic involvement of the lung was the rule.

Dr. M. Howard Fussell of Philadelphia observed that the papers demonstrated the as yet lack of unanimity of opinion regarding the epidemic of the fall of 1918. The futility of irritating applications to the chest in the attempt to reduce exudate in the lung he thought was also well shown. In the matter of referred pain in pneumonia he called attention to the fact that many abdomens had been opened with the thought of the presence of appendicitis or gallbladder disease, and emphasized the statement heretofore made that no case of supposed abdominal condition should be operated upon without careful examination of the lungs. He agreed with Dr. Litchfield regarding the value of giving large amounts of water in pneumonia, believing that nothing so reduced the toxemia. Not only was moving air a necessity, but it must be literally fresh air. The routine use of opiates was condemned, but in selected cases he would favor the administration of a small dose of opium rather than allow the patient to suffer the exhaustion of two sleepless nights. The occurrence of acute gastric dilatation subsequent to the crisis in pneumonia he thought was not as well known as it should be. Careful diagnosis in the late stages of influenza was urged that such cases might not be regarded as tuberculosis.

Dr. A. T. Livingstone of Jamestown, N. Y., expressed his surprsie that there had not been mentioned the basic factor in pneumonia or other inflammation, namely, disturbance of the circulation. He believed ergot to be the only drug which acted upon the abnormally dilated capillaries.

SECTION ON MEDICINE.

First Day—Tuesday, September 23.

Address of the Chairman.—Dr. George E. Holtzapple of York emphasized the necessity of cooperation for the accomplishment of the best medical work in a community. With a National Department of Health, a State Board of Health, local boards of health, full time health officers, and laboratory experts there would be no need for self-appointed enthusiasts who attempted to inaugurate legislation which would rob the physician of his liberty and individuality and his incentive for initiative which had resulted during the past in unparalleled research work upon which had depended medical progress. He felt that the profession should deprecate all forms of social health insurance, lodge and contract practice, except in localities in which medical service could not otherwise be obtained. The appointment of men to political posts examining for life insurance, and the rendering of surgical service to railroad companies did not militate against the progress of medicine.

Community Service to the Insane: Organization.—Dr. Clyde R. McKinniss of Pittsburg said the cost of maintenance of insane patients in the State Hospitals of Pennsylvania during 1918 was $2,969,961.30; in addition the amount expended by county and municipal hospitals was approximately $1,000,000. Yearly admissions to the hospitals of the State were about 5,296. In Pittsburgh on May 1 the commitment from police stations had been discontinued and there had been organized a ward in the hospital department of the Pittsburgh City Home and Hospitals for all mental cases coming under the observation of the Department of Charities. As a result of this departure, of 123 patients under observation 52 were committed, the balance being returned to their homes. Under the former method there would have been 123 commitments. Since the problem of the insane in Pennsylvania attracted several agencies now working independently it would seem to the mind of the writer desirable that they be brought together in the form of a section of the Pennsylvania State Medical Society. Here plans might be formulated for the extension into every community of the State an organization to promote better mental health, and to improve the care and medical treatment of the already mentally sick.

The Duty of the State.—Dr. Owen Copp of Philadelphia said that the first duty of the state concerned the welfare of its citizens as the basic condition of prosperity. There was just dawning in the public consciousness the conviction that a governmental policy of inaction in mental hygiene was wasteful of puhlic money as well as of human life and happiness. In this connection the state government had a profound

obligation and should recognize that insanity was a disease and therefore a public health problem. The dominant figure must be the physician in general practice, the family physician, who saw the disease in its incipiency. Medical education in mental and nervous disorders should be as adequate as in surgery and internal medicine. Community service to the mental patient was regarded as the essential agent in prevention. It was believed that an enlightened state policy under the inspiration of the State Medical Society would evolve an ideal hospital system for the care of mental patients and efficient measures in the prevention of insanity.

Dr. J. Allen Jackson of Philadelphia said that the absolute necessity for community service for the mental patient had been demonstrated. While excellent work was done in the neurological dispensaries and psychopathic wards of hospitals, parole patients would not report to the dispensaries and the hospital could not indefinitely supervise them. Whether community organization should be under state or municipal control depended largely upon whether state or county care was in vogue. In large cities he believed that the department of public health and charities should have a municipal bureau of mental hygiene, with psychiatric centers, or mental clinics. From this bureau patients would be referred to the appropriate hospital department, or direct to the hospital for the insane when the psychosis was incurable.

Dr. William W. Richardson of Mercer said that the state should insist that in the county institutions for the care of the insane there should be installed a resident physician capable of handling the problems involved. He had knowledge of such institution in which the only medical care was that given by the occasional visit of the general practitioner. He felt strongly that upon so important a matter the State Medical Society should take a determined stand.

Dr. Copp, in closing, said it was the imperative duty of the general practitioner to inform himself concerning the needs of the mental patient, since he it was who saw the disease in its very beginning. Failing in this the patient was liable to be shunted off to jail or detention ward instead of being sent to the hospital for the much needed treatment. He urged that the State Society take an active interest in this subject, which was costing the state millions of dollars.

Prevention of Communicable Respiratory Diseases, Based Upon Observations in the Army Camps.—Dr. Orlando H. Petty of Philadelphia detailed the sanitary measures enforced in the camps. Personal hygiene had been taught on all occasions, and special emphasis placed upon droplet infection. In the prevention of infection the properly fitted gauze mask, changed when soiled, had proved probably the most valuable agent. The value of bacterins in the prevention of communicable respiratory diseases had not been proven. Prevention, he believed, was to be accomplished, not by the injection of polyvalent preventives, but by the tireless enforcement of the difficult procedures of sanitation, hygiene, and preventive medicine.

Dr. M. Howard Fussell of Philadelphia observed that there was no easy road to the prevention of respiratory diseases. So far as known, the most readily preventable diseases were smallpox, typhoid fever, and, just possibly, pneumonia. The prompt isolation of cases of ordinary infectious colds would greatly limit the cases of respiratory disease. He regarded Dr. Petty's stand concerning bacterins extremely sane; personally, he was not sure that bacterins were entirely harmless.

Dr. Charles A. E. Codman of Philadelphia believed the sanitation of the army camps entirely applicable to civil practice, and coincided in the opinion that the value of bacterins was yet to be demonstrated. The mask which in his experience had proved to be the most efficacious was the ordinary chloroform inhaler, moistened with bichloride solution, and fastened with elastic bands about the ears.

Dr. Arthur C. Morgan of Philadelphia claimed that the remarkable advance in the medical work of the army made between 1898 and 1919 had been due in large part to the Reserve Corps men, who injected new life into the work, putting the Regular Army on the defensive. As a matter of economics he would recommend that in the return to civil life young men who had been members of medical detachments be selected for health officers. Their training had been such that should make them 100 per cent. efficient.

Dr. Thomas H. A. Stites of Hamburg felt that there should be made public more specific directions upon the proper way of wearing the mask. In ordinary hygiene he regarded the washing of the hands on every possible occasion important in the prevention of transmission of communicable disease.

Dr. C. P. Brown of Ambler, from his laboratory and army experience, believed that while not entirely proven that the pneumococcus vaccine was the answer to pneumonia, it was entitled to much more use than it had received.

Epidemic Cerebrospinal Meningitis Diagnosis and Treatment.—Dr. Joseph Sailer of Philadelphia said that the two features of importance in the management of meningitis were prophylaxis and serum treatment. Prophylaxis was to be accomplished by the recognition, segregation, and treatment of carriers. Chronic carriers might require segregation for a long time, and there was no known certain method of clearing them. Treatment of the disease by serum was specific and the most important method of administration was intrathecal. The intravenous administration might also be employed, particularly in cases in which either as a result of culture, general blood infection was found or in which there was evidence by purpuric eruption, or in case there was evidence of localization in some of the internal organs. The amount of serum should be the most that could be safely administered; it should be given from one to three times a day in the early stages and at the earliest possible moment in the case. The efficacy of vaccines was still in doubt.

Dr. Lawrence Litchfield of Pittsburgh said that in two cases of meningococcic pneumonia in the early part of his army service he had given Flexner's serum intravenously and in all his meningitis cases he had given it intraspinally. It had seemed to him that the cases did better; both men with the pneumonia had recovered. In his meningitis cases refusing water, or in which a sufficient amount could not be given by the bowel, he had found the very free use of dextrose intravenously was often of decided benefit, and in many instances apparently life saving.

Dr. M. Howard Fussell of Philadelphia commented upon the refusal of boards of health to isolate cases of meningitis. He had personally requested that such isolation be carried out in the general hospital and had been refused. He felt that results with the serum treatment of meningitis had been better at the time of its first being advised by Flexner, and asked whether any difference had been noted in the serums made by different manufacturers.

Dr. B. Franklin Royer believed that much depended upon the time during the epidemic when the serum was administered as well as upon the disease itself. When given as early as the second day he had secured the more satisfactory results.

Dr. Thomas Klein of Philadelphia referred to his treatment in 1918 of a number of cerebrospinal meningitis cases in Dr. Sailer's service by means of antimeningococcic serum intravenously. In a series of 77 cases the mortality had been 18 per cent. At that time and at Camp Dix it had seemed that the intravenous administration obviated the necessity of the large dose in the spinal canal, and in that respect alone he thought the intravenous method an advantage over the intraspinal. In cases not treated by the serum the mortality was about 40 per cent. The intravenous administration was begun as early as possible, with 50 c. c. diluted, repeated every eight or sixteen hours as demanded.

Dr. Sailer, in closing, referring to Dr. Fussell's request for isolation of meningitis cases in the hospital, cited an intance of ward epidemic in which the cases were traced to one nurse found to have virulent meningococci in the naso-pharynx. He believed that in all cases of meningitis isolation of the most careful character should be instituted. That ward infection was rare was no reason why every possible precaution should not be taken.

The Present Status of Therapeutic Pneumothorax in Pulmonary Tuberculosis.—Dr. Alexander Armstrong of White Haven expressed his conviction that thera-

peutic pneumothorax was the only new plan of treatment for pulmonary tuberculosis discovered in recent years which had positive value. Selection of the appropriate case required careful physical diagnosis and usually several weeks of close observation of the patient. Progressive softening was the indication most often calling for compression of the lung. Remembering that pleurisy was usually a forerunner of tuberculosis the treatment should be employed early. He urged that in every town of over 10,000 inhabitants one physician familiarize himself with the plan of treatment.

Dr. ISADORE KAUFMAN of Philadelphia emphasized the necessity for care in the selection of the case for this treatment and cautioned against the recommendation that the procedure be carried out by the general practitioner. The treatment was preferably to be carried out by a surgeon working under the direction of a man familiar with the disease.

Dr. ARMSTRONG, in closing, said that to wait for a period longer than six weeks before administering the treatment was almost criminal negligence. Although therapeutic pneumothorax was in a measure on trial, he felt the patient with pulmonary tuberculosis should be given the chance it offered.

Second Day—Wednesday, September 24.

The Value of an Early Diagnosis of Pleural Effusions.—Dr. S. A. SAVITZ of Philadelphia observed that it was well to consider all serous exudate as tuberculous. In the study of the chest he regarded percussion as the dependable practice and its variation upon change in posture as the cardinal sign. Palpation and auscultation he believed of little value, but emphasized the importance of the frequent use of the aspirating needle. Pleural effusions, he said, were too frequently mistaken for other respiratory diseases. An individual with a pleurisy, discharged from treatment too soon, or with a pleurisy unrecognized, undoubtedly had a passive lesion which might become active. Too much emphasis could not be laid upon the importance of keeping such patients under observation for a long time. Since the recent war had shown that there was as little danger in opening the thorax as the abdomen, he felt that by closely watching the pleura and working in conjunction with the surgeon tuberculosis might be greatly lessened.

Dr. ARTHUR C. MORGAN of Philadelphia spoke of the great importance of Dr. Savitz's paper in its reference to the development of pleurisy and tuberculosis in the same individual. In his experience in teaching students he had records of at least seven students developing pleurisy, with or without effusion, who had died of tuberculosis. To him, pleurisy with or without effusion, did not mean "predisposition" to tuberculosis, but that the patient was really the subject of tuberculosis. Contrary to the author of the paper, he believed auscultation of the chest in pleurisy of value for the quality of the voice, the slight changes in breathing, amplification of the tubular sounds, under the scapula, particularly on raising the arm, all having an important bearing.

Dr. JOSEPH SAILER of Philadelphia agreed with Dr. Morgan that percussion was not the dominant physical method, but regarded inspection, palpation, and auscultation particularly, as of extreme value. That simple puncture was not unattended with danger should be remembered and more care regarding it should be exercised than had been the custom. At Camp Wheeler there had been two deaths from simple puncture, both sudden; one just at the end of the operation and the other a few minutes later. Autopsy had shown no other cause of death. Granted that all cases of pleurisy were tuberculous, which Dr. Sailer regarded as an overstatement, many pleurisies could be tapped and the patient be healthy for a long series of years.

Dr. CHARLES A. E. CODMAN of Philadelphia regarded the differential diagnosis between some pneumonias and pleurisies as extremely difficult. Too great dependence should not be placed upon the method of diagnosis. An encapsulated pleurisy presented difficulties in diagnosis, as did the differentiation of sarcoma of the lung and an effusion.

Dr. WILLIAM G. TURNBULL of Cresson felt that the danger of puncture in effusion was not sufficiently appreciated, for tuberculosis cases had developed empyema as a result of unwise aspirations of pleural effusion. In an institution with over a thousand cases of tuberculosis in a year he attributed the small number of two empyema cases to the fact that the resident physicians were not permitted to use the aspirating needle.

Pulmonary Syphilis.—Dr. ELMER H. FUNK of Philadelphia here dealt more particularly with late syphilis of the lung, which he said most commonly manifested itself as gummata occurring usually near the root or in the lower lobes. These might occasionally break down, forming small cavities. The gummata might also be converted into fibrous tissue and the resulting contraction distort the lung, giving rise to bronchiectasis. Gummata had been found at autopsy in those who during life had given no evidence of pulmonary disease. Syphilis of the lung, the author said, might manifest itself as a diffuse fibrosis. Lesions of this character, it was said, could not be attributed during life from fibrosis due to tuberculosis, and the autopsy evidence might even be inconclusive. While not in sympathy with the frequent diagnosis of syphilis of the lung, upon scant evidence, it was Dr. Funk's belief that it occurred clinically more often than older observers believed and than post-mortem evidence indicated. With Hofman he believed that patients had unnecessarily died from pulmonary syphilis improperly treated under a mistaken diagnosis of pulmonary tuberculosis or other condition.

Dr. E. J. G. BEARDSLEY of Philadelphia cited a case illustrative of the uncertainties and difficulties in pulmonary tuberculosis. In the patient who was believed to have an advanced tuberculous sputum, examinations had been continuously negative for tubercle bacilli. The blood gave a four plus Wassermann. At this time the forty-second sputum examination revealed myriads of acid-fast bacilli.

Dr. WILLIAM A. WOMER of New Castle cited a case in which repeated sputum examinations were negative, but in which a history of chancre had been obtained. Under antisyphilitic treatment the condition cleared up, the sputum, of which there was a quart or more daily, almost disappeared, and the man had apparently entirely recovered.

Dr. FUNK, in closing, said that while the finding of the bacilli in Dr. Beardsley's case would seem to establish the etiology of the lesion, he would want a second positive to check the examination. The instance did not in his opinion militate against the statement that in all patients with long-standing symptoms, with definite signs in the chest of advanced lesions, and in whom the sputum was repeatedly negative, the lesions were as a rule nontuberculous. Disbelief of this statement and failure to make it the working rule would cause the physician to miss the large majority of nontuberculous conditions, for here was the turning point in the diñerential diagnosis between advanced pulmonary tuberculosis and other conditions.

Removal of Spinal Cord Tumor, Resulting in Entire Disappearance of Paraplegia and Neurological Signs.—Drs. THEODORE DILLER and OTTO C. GAUB of Pittsburgh contributed this paper, which was read by Dr. Diller. The case was that of a healthy woman 28 years old who had for two years suffered from increasing weakness in the legs, resulting in complete paralysis. There were pain about the anal region and impairment of sensation from the level of the navel downward, with exaggerated knee jerks. At operation a tumor about the size and shape of the little finger was found encircling the spinal cord below the level of the ninth thoracic vertebra beneath the dura. Its removal was easily accomplished and it was found to be an endothelioma. The cord was indented but apparently uninjured. Movement of the toes was possible on the following day, and at the end of two months the woman was able to walk. Sensory changes disappeared within two weeks; knee jerks became normal, and ankle clonus and Babinski toe reflexes were absent.

Dr. JOHN A. LICHTY of Pittsburgh cited the cases of two women with distinct paraplegia and symptoms corresponding to those described by Dr. Diller. One had entered the hospital with a tentative diagnosis of pelvic disease producing pressure. Following a positive

Wassermann, salvarsan was administered intravenously, with mercurial inunctions and iodides. In eight weeks the woman was able to walk. In the second case in which the Wassermann was also positive, recovery followed the appropriate treatment, except that there remained to a recent date loss of sensation about the buttocks and anus and upon the inner side of the thighs. In both patients there had been sore throat previous to the spinal symptoms and it was thought that an influenzal infection might have caused the neurological disturbance.

Dr. JOHN J. GILBRIDE of Philadelphia reported three cases he had seen of the type described by Dr. Diller, one of which was in his own service. In two the lesion was extramedullary; in the third, intramedullary. It had been his observation that the lesion was higher in the cord than was shown by the clinical examination, and that operation upon two of these vertebræ above the supposed location of the lesion was necessary.

Dr. DILLER, in closing the discussion, said that there had been some occasional loss of control of the bladder and bowels in his case. In an operation of the kind described he felt that the work was too exhausting for one surgeon, that there should be a second skilled operator to do the very delicate manipulation required.

Sexual Psychoneuroses as Studied in a Medical Clinic. Dr. E. J. G. BEARDSLEY of Philadelphia presented a study of a series of adolescent patients suffering from anxiety neuroses due to overstimulation of the sexual centers. Functional nervous conditions he said should have as careful investigation and treatment as organic illnesses. There was urgent necessity that parents be instructed regarding sexual hygiene, and he felt that intelligent, sound advice from official sources should be encouraged. The diagnosis of sexual anxiety states was dependent upon the elimination of organic disease by careful physical and laboratory examinations, and in the average patient recognition of the true cause of the symptoms was said to render cure a certainty. Careful inquiry was advised into the sex life and thought of the functionally nervous patient during the adolescent period.

Dr. THEODORE DILLER of Pittsburgh, in his examination of a considerable number of young men in the Army complaining of nervous and mental symptoms, had made the diagnosis of constitutional mental inferiority. In treatment there was needed, first of all, a good neurologist who would take a personal interest in the man; then hydrotherapy and psychotherapy in a good institution.

Dr. TOM A. WILLIAMS of Washington. D. C., regarded the anxiety state as often due to its combination with some physical phenomena; unfortunately it was frequently exaggerated by unwise and unskillful meddling of medical men who, not realizing that the condition was due merely to a psychological attitude of the patient, spoke of it before the patient as a serious physical disturbance. Treatment of the case consisted in making a correct estimation of what was taking place in the patient physically and mentally, and enabling the patient to understand what was taking place. This latter was accomplished by entering into the patient's way of thinking and leading him out of the situation so that he saw himself truly and ceased to have about himself sensations which were morbid, but in their place feelings about himself which were true. Patients disinclined to so reveal themselves could be persuaded by the art of psychotherapy.

Cardiovascular Phenomena Associated With War Neuroses—Dr. GEORGE MORRIS PIERSOL of Philadelphia expressed the opinion that medical officers were in accord that chronic organic disease of the heart played an inconspicuous rôle among the medical casualties of the A. E. F. Of 3,752 medical cases in one base hospital. only 24 showed definite organic disease. This incidence, however, by no means represented the number of apparently healthy soldiers in whom from time to time systolic murmurs were observed. That the cases designated as "effort syndrome" came under the supervision of the cardiovascular examiners and medical men rather than of the neurologists he thought was probably due to a misconception of etiology and mechanism and because symptomatically the cases were so obtrusively cardiac. It was a source of pride to Americans that they owed the recognition of the syndrome to DaCosta who, in 1871, published his "Irritable Heart of Soldiers." From the various observations made of "effort syndrome" Dr. Piersol thought it justifiable to regard it as the result of the reaction of an unstable nervous mechanism to anxiety and overstrain, producing a neurosis associated with cardiovascular symptoms, just as in other instances the same factors induced neuroses in which the well-known symptoms referable to the gastrointestinal tract and musculoskeletal systems occurred. Cohn had observed that after the signing of the armistice "effort syndrome" had been difficult to discover. In treatment of the affection the lead of the British had been followed, the cases grouped in detachments and given systematically graduated exercises and practice marches, always in military formation. In addition the men were encouraged to play games and were diverted by amusements. The results in the army had been so encouraging that the method had been applied in all convalescent medical cases fit for mild exercise. Dr. Piersol thought the plan of treatment might with economic advantage to patient and hospital be introduced in civilian hospitals, although the average civilian patient might not take kindly to "setting up" exercises, or to anything diminishing the comfort of his convalescence. The belief was expressed that the experience gained with large numbers of soldiers suffering from "effort syndrome" had awakened a true appreciation of the frequency with which neuroses manifested themselves through symptoms referable to the cardiovascular system.

Significance of Heart Murmurs Based Upon Examinations in the United States Army.—Dr. EDWARD H. GOODMAN of Philadelphia said that the question of murmurs as it appeared to him was that diastolic murmurs generally indicated valve disease and that systolic murmurs might or might not do so. He called attention to the fact that mitral stenosis and aortic insufficiency were seriously regarded simply because the diagnosis had been made from the murmur, and that, he thought, was about all that had been learned from the murmurs. It was known that these lesions were serious because the myocardium suffered most and because nearly always eventually decompensation was present. This eventuality was not necessarily recognized by the murmur; recognition might be by the most casual inspection. While murmurs were useful for diagnosis, the chief concern of the patient was his margin of safety and how much the valve lesion would shorten his days. Prognostically, except always in mitral stenosis, diastolic murmurs alone were of questionable value. With the systolic murmurs the case was different; some were innocent, others not, and it was important to distinguish between them. Here, as in the case of diastolic murmurs, the greatest importance lay in the behavior of the muscle. To diagnose a case one of aortic insufficiency was of service in prevention of overexertion; to estimate the efficiency of the heart muscle would emphasize the insignificance of murmurs.

The Early Recognition of Diseases of the Heart.—Dr. THOMAS MCCRAE of Philadelphia stated that the lengthened average duration of life was due to the decreased death rate in the earlier years of life; that for the ages over fifty the death rate from diseases of the circulatory system appeared to be increasing. The important points in the attempt to lessen this increase were an endeavor to reduce the injury resulting from acute infections, and the recognition of the earliest signs of disease of the myocardium. In both instances the chief concern was with the myocardium. The alertness of the general practitioner in his opportunity to see early cardiac conditions meant much to the patient. The following etiological classes were discussed in detail: (1) Acute Infectious Disease; (2) Syphilis; (3) Subacute and Chronic Infections; (4) Arteriosclerosis; (5) Renal Disease. The points to be given particular attention during and following infectious disease were, rate, rhythm, character, heart, lungs, and blood pressure. In every case of syphilis, myocardial involvement should be regarded as probable. In subacute and chronic infections special attention should be directed to infection of the gallbladder and

prostate in the prevention of serious myocardial changes. With a chronic bronchitis there might be damage both from the infection and from the mechanical effects of coughing. In arteriosclerosis when cardiac symptoms appeared the damage, as a rule, was already accomplished. In the means of recognition of early acute cardiac disease the author placed emphasis upon the importance of the myocardium and cautioned that the interest of endocarditic and pericardial disease should not detract from the study of the state of the muscle. In endocarditis two forms demanding particular care were the aortic lesion of syphilis, and the endocarditis of rheumatic fever, especially in children. The recognition of myocarditis was stated to be the most important part of the problem, and first in value here was the use of the electrocardiograph.

Dr. A. E. Roussel of Philadelphia pointed out that Mackenzie had written much concerning the insignificance of systolic murmurs in the second and third decades of life. Observations made by the war examiners had been drawn largely from those decades, and Dr. Roussel cautioned that these murmurs had a much greater relative importance after that period of life. In mitral stenosis the nitrite of amyl test in which the patient broke the capsule, passing it in front of his face, was to Dr. Roussel of particular value. In many instances the murmur would come out where before it had been only suspected. A test, partially original in his own observation, was that of the influence of ocular pressure which he had mentioned two years ago in the meeting of the American Medical Association and to which Major Rothschild had referred in the *Journal* of the Association without credit to him.

Dr. Charles Rea of York endorsed the note of warning given by Dr. Piersol that all evidence should be weighed in cardiac cases. In determining the presence of presystolic murmur he had found helpful the principle that when there was uncertainty of just when the first sound began, a presystolic murmur was present.

Dr. Arthur C. Morgan of Philadelphia reported in a series of 1,400 men examined at Camp Lee a large number of "effort syndrome" cases in which the men were classified for domestic service and rushed overseas. At Camp Lee there had been found a large number of men with palpable thyroids from the western part of Pennsylvania. This he felt offered a field for investigation by the Public Health Service, believing that the eradication of hyperthyroidism would make for efficiency in the coming generations.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 1, 1919.

The First Vice-President, Dr. Reginald H. Sayre, in the Chair.

Efficiency and Sanitation in the Feeding of the United States Army.—Colonel John R. Murlin, U. S. Army, delivered this address by invitation, which he illustrated by motion pictures and lantern slides showing the methods of inspection, preparation, and distribution of food at the various army camps throughout the country. He stated, in part, that his first experience in the army was at the Plattsburg Training Camp, where he happened to be the victim of food poisoning. This experience brought very forcibly to his mind the necessity for care in the selection and adoption of sanitary methods in the handling of food in army camps. He spoke to the commanding officer about the food question and as a result was asked to make a survey of the conditions in the camp with reference to efficiency and sanitation in feeding the men in training. The report of this survey was sent to the Surgeon General's office in Washington. He then received an invitation to come to the Surgeon General's office for the purpose of organizing a Division of Food and Nutrition as a part of the Medical Department and not under the Quartermaster's Department, which up to this time had had entire control of the feeding of the army. The Surgeon General was much interested in the proper and sanitary feeding of the troops, so that any effects on the health of the troops due to improper food would not be laid at his door. He succeeded in convincing the War Department that the sanitary feeding of the army was primarily a medical problem.

As a result of these preliminaries a considerable number of laboratory workers, physiologists, biochemists, and experimental workers in this field were called together to draw up plans for the efficient and sanitary rationing of the army. In 1917 there were many complaints in regard to food wastage in the army camps, which it was claimed were interfering with the plans of the Food Administration for food conservation. A conference was held at Hoover's headquarters in Washington composed of the Board of Alimentation of the Council of National Defense and representatives of the Army, Navy, and Food Administration. A discussion took place at this conference during which it was proposed that a nutritional survey be made of the camps to determine whether food was being wasted and what were the actual food requirements of a soldier in training. Early in March, 1918, General Shaffer and several officers were sent to England and France to study the food problem in the armies in those countries. In June twenty men were added to this commission and in October ten more were added. Major Carleson, who had charge of the rest camps in England, found that our troops who were on the British ration at that time were complaining. The British ration was small in comparison with that of our soldiers in this country, being only 3,000 calories, whereas that of the soldiers in the camps in this country was 4,000. As a result of the investigation made by Major Carleson and Majors Winters and Biddle, measures were taken whereby our troops were supplied with a ration substantially like that of the men in training in this country. In France the work consisted in the inspection of food shipped to our troops at various points along the line until it reached the troops in the front lines and in the actual war zone.

The results of the nutritional survey of the camps in this country from the physiological point of view was interesting, because it showed just what troops ate while in training, how much food they consumed, and how much they wasted. In the early part of the war the sanitary arrangements for guarding against deterioration in the food and careless handling were inadequate. This could not be blamed on the Medical Department as the Quartermaster's Department had charge of the feeding of the army, but after the Medical Department became interested in the question the Quartermaster's Department usually put into practice the advice given by the Medical Department. A surveying party usually consisted of four selected officers and several non-commissioned men, and every camp was visited once, some twice, and others three times. A number of messes were selected in each camp as typical of the amount of food supplied, the amount of food consumed, and the amount of food wasted.

The ration supplied to an army in the field was much larger than that supplied to an army in training, and this was because of the inevitably larger amount of waste and not because a fighting army required more food than an army in training. The ration for a man in the fighting lines was 4,500 calories. The average ration of the different allied armies in training on May 1, 1918, was as follows: British, 3,500 calories; Canadian, 3,000 calories; French, 3,500 calories; Italian, 2,700 or 2,800 calories. When in the field the British had about 4,000 calories and when in an actual engagement 4,300. The Italian ration in the field was about 3,400 calories. The ration supplied to the American army during the early months of the war was the same as that of the training camps, and it was issued every day alike. As a result of the nutritional survey it was modified in 1918. Late in November, 1918, a new ration was supplied in which a distinction was made between the winter and summer ration. In the winter about 5,000 calories were supplied and in the summer 4,600. Accurate data were secured on 427 messes as regarded the average amount of food consumed at different seasons of the year, from which it was found that the average amount consumed from October 1, 1917, to December 1, 1918, was 3,635, or a little more than the average consumed by the farmer. There was an average waste per man of 0.38 pound of edible food, which was well below the average for the civilian population which was ½ pound a day. Since that time an im-

provement had been made in regard to waste. These figures furnished a pretty satisfactory refutation of the statements regarding the large amounts of food wasted by the army.

It was found that troops usually lost in weight during the first week in camp, owing to the change in food, the necessity of the men adapting themselves to new surroundings, and the fact that this was the period of inoculation. The amount of food consumed by this series of men was from 2,500 to 4,500 calories per man per day. There were just as many men taking more than the average as there were men taking less than this average, and the significance of this was that there was no special factor that controlled the amount of food consumed per man per day. The curve showing the amount of food taken per day by these men was a typical biological curve and was altogether a matter of chance. The soldiers as they came from the draft boards stood just as good a chance of getting 4,000 calories as they did of getting 3,200. The variation in the amount of food consumed per man per day by months from October 1, 1917, to December 1, 1918, showed that the amount was increased from October to March and that it was lower during the summer and fall, when it began to start up again. We had always been under the impression that we ate more in winter than in summer, but this was the first actual demonstration of the fact; however, the difference in the amount consumed in winter and in summer was not as great as was supposed. A man of average weight, about 146 pounds, took only 400 calories less in summer than in winter. The fact that the difference was not greater was due to the difference in muscular activity in winter and in summer. The tables showed a gradual increase in the cost of food as the war progressed and this was due, of course, to market conditions. The tables also showed the improvement in the matter of waste. After the armistice was signed there was a general relaxation of the morale of the men and the mess efficiency fell below par, so that there was a larger waste of food in November and December, 1918, than in the previous months.

In studying the food question in reference to the soldier another factor that had to be taken into consideration was the food purchased and eaten at canteens. The troops were free to purchase and eat anything they liked at the canteens. The articles of which they purchased the largest quantities were candy, soft drinks, pies, and cakes, and to a less extent fruit. They purchased an occasional meal just for a change of flavor. The fact that a man ate at the canteen or the mess seemed to bear no relation to the amount of food he consumed. It could not be shown that a man ate less at mess, because the food was poor, or more at the canteen, because he liked the food better. Comparing the cost of food at mess and at the canteens showed that the food purchased at the canteens cost three times as much as the Government spent for the food supplied at mess. The canteen was therefore very expensive, but it had a place in sustaining the morale of the men and giving them social recreation. As a feeding institution the canteen was an expensive proposition. They had tried to find whether the cost of food at the canteens had any relation to the amount consumed and found that that was also a matter of chance. A comparison of the amount of food consumed in the army was made with that consumed in various occupations, as shown by an investigation conducted by the Bureau of Home Economies, Department of Agriculture, in which 110 families were studied, selected at random. Among different groups of people represented in these families from 2,500 to 3,500 calories per person per day were consumed. The average for the farmer was 3 600 calories per day. As a result of the work of the Interallied Commission it was found that the per capita consumption in this country was a little higher than it was in England. The consumption in different occupations was highest among farmers; professional men came second, teachers third, and laborers fourth. In comparing the work of the soldier with that of other occupations, it might be characterized as a little harder than that of the farmer, but not as hard as that of the mason or lumberman in the winter when he rolled logs all day. In comparing the amount of different articles of food consumed by the soldiers with that consumed by the civilian population, it was found that the army consumed twice as much fresh meat and more than twice as much smoked and preserved meat. The army consumed twice as much bread and beans, one and one-half times as much potatoes, about the same amount of sugar, and considerably less flour. The army used a great deal more canned milk than the civilian population; nearly all the milk used by the amy was canned. In fact it was quite characteristic of the diet in the training camps that the food was in a more concentrated form. The army used comparatively few fresh vegetables, as compared with the civilian population, and comparatively little fresh fruit. On the other hand, the army used large quantities of dried fruits, as compared with the civilian population. As to the number of different articles of diet, the army used on an average fifty to fifty-five articles of diet when in training. The number of articles used in the officers' mess was much greater than in that of the privates. The mess sergeant was given a good deal of liberty in the purchase of food and was allowed to buy as much as one-half the food required from outside sources, but he was not permitted to buy articles of food outside that he could buy from the Quartermaster's Department. The number of articles of food found to be eaten by the civil population was found to be on an average from thirty-five to forty. The Government did not buy food or supply cooks to the officers. They were compelled to manage their own mess. When the troops took to the field the number of articles of diet fell to fifteen or thereabouts. The percentage of the various food constituents was as follows: Protein, from 10 to 15 per cent.; fat, from 20 to 40 per cent.; carbohydrates, from 45 to 70 per cent. The mean proportions were: Protein, 14 per cent.; fat, 31 per cent., and carbohydrates, 55 per cent. The comparative percentage of cost of different articles of food were: Meat, 42 per cent.; fresh meat, 22 per cent., and the rest was canned meat of different kinds. Bread formed about 6 per cent. of the diet, sugar 5 per cent., and a variety of articles of food in quantities too small to chart made up the remaining 7 per cent. Other charts showed the increased cost of food during the latter part of the war as compared with the cost in the beginning of the war. The Quartermaster's allowance for food had not been increased in proportion to the increase in the cost of food. It was an advantage for the mess sergeant to buy from the Quartermaster's Department when he could, as he then got supplies at wholesale prices. The cost of food, of course, varied from time to time and from place to place. The cost jumped immediately after the armistice was signed. The survey parties had tried to see what could be done in the way of influencing economy in food and in preventing anything being thrown away that could be eaten. The mess personnel were given instructions in cutting and serving and in the use of leftovers, and it was interesting to see the results after they put these instructions into practice. A chart illustrated what had been done in one regiment. Before the methods of economy were instituted the average waste was 0.6 pound per man per day, and afterward this was reduced to less than $\frac{1}{10}$ pound per man per day. The men were not allowed to leave anything on their plates. They could have all they wished to eat, but nothing must be left. A similar reduction in waste was shown at other camps after the introduction of these methods. In April, 1917, a second survey was made. That the reduction in waste placed no harmful restrictions on the troops was shown by the weight curves. Accurate data were kept of 523 men, and at the end of five months all these men weighed and measured more than before they went into training. The average increase in weight was 6.6 pounds and this increase was evenly distributed throughout the different organizations among both large and small men. Another investigation made by the survey was as to whether the large amount of meat eaten by the troops was deleterious in view of the impression that a diet with a high percentage of meat was harmful to health, since it might be productive of high uric acid. The ash of meats and cereals was acid, while that of fruits and vegetables was alkaline. Therefore if one ate a high percentage of meat he should also eat a large quantity of fruit and vegetables to neutralize the acidity. Investigations at Camp Cody showerd that there was a slight predomi-

nance of the acid ash. If the diet was assayed as regarded the ash content, it was found to be really an acid diet; but observing the men for a longer period, it was found that they took enough alkaline food to counteract this effect, with the result that the average showed at about the neutral point. The hospital diets, on the other hand, were alkali. This was explained by the fact that in the hospital the regular diet consisted largely of milk, which was a neutral diet, and of fruit and vegetables, and the striking point brought out was that this was the diet generally used for the sick man. The average hospital diet was almost neutral.

The interesting thing in the work of the Medical Department was that sanitary suggestions were adopted to the end that the food might be wholesome and clean. This end had been achieved in this war as it had never before been done during war. The result had been a healthy body of men. There were almost no reports of food poisoning or of any untoward effects that could be attributed to the character of the diet. The credit for this accomplishment was due to the Special Division on Food and Nutrition. One nutritional expert was assigned to each camp. Instructions were given in the selection and buying of food. In reference to meat, these instructions were such as served to inform the buyers how to purchase meat that was muscle and not bone, and how to look for spoilage. The army purchased only male beef. The pictures showed the methods applied to ascertain the state of preservation of smoked and canned meats and of other canned goods, cereals, etc. Other pictures showed the method of baking bread. Colonel Murlin stated that the army bread was as good bread as one would find anywhere. The methods of refrigeration were shown and it was explained that the temperature of an icebox was not as low as most persons were accustomed to think, the average temperature being about 45° F. The method of dishwashing in the army had also been revolutionized during the war. In the beginning of the war it consisted in dipping the dishes successively in large vessels of hot water, but as the water cooled so rapidly all dishes did not have the benefit of hot water and consequently were not sterile. A new method was then introduced by which the dishes, heaped in wire baskets, were immersed into tanks in which the water was maintained at the boiling point by constant entrance of boiling water. Following the employment of this method of dishwashing, it was observed in one camp that the incidence of influenza was only one-eighth as high as before. As a consequence of the work done during the war the Division of Food and Nutrition was now firmly established in the army, and the General Staff had decided to retain it as a part of the Medical Department. In this way the feeding of the army was placed on a professional basis. In the future the training a young medical officer would receive would include an advanced course in food and sanitation, and these medical officers would not only know the value of foods, but they would know the details of messing and would know how to apply their professional knowledge in this line.

Centenary of Auscultation.—The year 1819 saw the publication of Laennec's treatise on mediate auscultation. Laennec, a Breton by birth, like many other illustrious physicians had his first medical experience as a military surgeon. In 1816 he was consulted by a young woman with heart disease. Direct auscultation proving unsatisfactory he, on the spur of the moment, rolled up a paper cylinder and listening through it, heard for the first time the unmuffled sounds of the heart. He worked heart and soul at his new discovery and got it in shape for submission to the Academy of Sciences in 1818. The stethoscope, however, was coldly received as a mere toy, even after the appearance of his book a year later. However, Williams of London became his warm disciple, as did other well known clinicians, and in 1823 Laennec, at the time a physician to the Charity Hospital, Paris, was awarded the chair of medical pathology in the Paris Faculty. His clinic was beseiged by physicians from every part of the globe, so that he was obliged to lecture in Latin. He succumbed, only three years after his appointment, to tuberculosis.—*Boletin de la Revista Ibero-Americana de Ciencias Medicas.*

Miscellany.

A Spanish Appreciation of the Late Dr. Mary Walker.—Under the title "Medical Feminism" Werey contributes an article on the death of Dr. Walker for *La Medicina Ibera* for July 12. He says that not only was her mentality most remarkable, but that she had great physical energy. As a girl, before receiving her medical degree, she was very attractive, but even the Venus de Milo would lose her charm if her apparel was unesthetic. The Civil War, in which she served as a medical woman, made her masculine garb not so unseemly as might have appeared to the esthetic sense. The present war has led to like practices, and even in Spain today women physicians sometimes wear trousers, although, of course, on special occasions only. Dr. Walker having once donned man's apparel never returned to the garb of her sex. This, of course, caused confusion of sex and lead to many happenings unpleasant to herself and a general belief that she sought only notoriety. The people of the United States, Dr. Werey says, sanction almost every form of personal extravagance in behavior which is not immoral, but in this case public opinion was unfavorable to her. She was, however, very well satisfied with her course and insisted to her women friends that "trousers were a grand thing." The writer can find no evidence that Dr. Walker ever had a love affair and cannot conceive of a woman who went always clad in trousers, frock coat, and sombrero falling in love. This custom was probably an emotional outlet which did away with the necessity for love. But aside from this weakness, or whatever one chooses to term it, the subject of the article is characterized by the author as truly an eminent woman.

Vital Statistics of Havana.—From the January number of the *Revista Medica Cubana* we extract the following data. While the number of births since 1901 shows in general a small increase, the fecundity shows a striking annual variation. Thus in 1914 it reached a maximum of over 10,000 while in 1913, 1915 and 1916 it was but little over one-half that figure. In 1917 and 1918 on the other hand it nearly attained the maximum. This registration is plainly erroneous, as such fluctuations in fecundity could not be possible. The marriages during 1917 and 1918 show that the excess of the latter over the former year was over 1,000. The number of marriages necessarily affects the birth rate but the great discrepancies in the latter from year to year must depend largely on the percentage which for any reason escapes registration. The laws must be enforced more rigidly in certain years. About a third of all births are illegitimate, divided about equally in numbers between whites and blacks. No evidence is adduced to show that illegitimate live births have any special tendency to escape registration. The percentage of still born children averages about ten and the legitimate exceed the illegitimate in a ratio of about 3 to 2. As in some countries this proportion is reversed it is possible that numerous illegitimate still births escape registration. The deaths in 1917 were 7,059 and in 1918 the total was 7,942. This increase was due to influenza.

COMPULSORY HEALTH INSURANCE—ITS PROMISES AND ITS DANGERS.*

BY E. MACD. STANTON, M.D., F.A.C.S.,

SCHENECTADY, N. Y.

CHAIRMAN, COMMITTEE ON PUBLIC INFORMATION, MEDICAL SOCIETY OF THE COUNTY OF SCHENECTADY.

FOR several years an organization, known as the American Association for Labor Legislation, has been conducting in this country an active campaign for Compulsory Health Insurance. This organization has been particularly active in New York State where they have succeeded in converting to their cause our Governor, several members of the Democratic State Committee, the officials, at least, of the New York State Federation of Labor, and, superficially at least, many of the woman's clubs, uplift organizations, and other bodies.

On paper the promises of those advocating Compulsory Health Insurance are certainly attractive. The New York bill known as the Davenport Bill promises that "Every insured person shall be entitled to receive as minimum benefits from the fund to which he belongs: Medical and surgical attendance and treatment, attendance by visiting nurses, medicines and medical and surgical supplies, hospital or sanatorium treatment and maintenance; dental service; cash sickness benefit; cash maternity benefit; funeral benefit." This sounds like a medical Utopia and because the vote for and against the project in the State Legislature, this coming winter, will undoubtedly be close, it is very important that we determine whether this is really a step toward better things or just an old fashioned "gold brick."

The propaganda for this measure has been carried on so far with a minimum of publicity. The agents of the American Association for Labor Legislation have for the most part gone direct to the heads of the organizations they have desired to influence. Take, for instance, the New York State Medical Society. Three years ago it was suddenly discovered that the American Association for Labor Legislation had converted one or two of the State officials, and the next thing the State Society knew there was an almost successful attempt made to use this as a basis for claiming that the State Medical Society had indorsed the project, although at that time 90 per cent. of the fifteen thousand members of the profession in this State had scarcely heard of such a thing as compulsory health insurance.

*Read before the Committee on Public Information, Medical Society of the County of Schenectady, Oct. 3, 1919.

I am quite sure that, if the members of this audience take the trouble to look into the matter, they will find that a number of the clubs or organizations to which they belong have gone on record in favor of compulsory health insurance, after no more careful investigation than a brief talk between one or two of the officers and an agent of the American Association for Labor Legislation.

We can get some idea of the tremendous importance of this measure when we stop to consider that there are in this State about 4,000,000 wage earners who are supposed to lose about nine days a year each from sickness. If all of the numerous and somewhat luxurious benefits mentioned in the bill amount to only three dollars per day, we would have the stupendous total of $118,000,000 to be distributed annually through a semipolitical organization created by the Compulsory Health Insurance Bill and controlled by the party in power. If we include the dependent members of their families the figures will be much larger. There would be thousands of inspectors and other salaried employees. In fact the administrative expenses to be borne by the State must increase to a tremendous extent the amount to be raised by taxation.

Important as are the financial considerations, they fade almost into insignificance when we consider the fact that with the adoption of this legislation we unquestionably reverse the very foundations of the policy of the State toward the individual. Instead of a policy calculated to stimulate individual initiative and self-help we substitute a policy of control of the individual and State help.

With some realization of the importance of our subject let us turn again to the promised benefits. All working people and the dependent members of their families adequately insured against the irregularly distributed risks of sickness and the financial losses incident thereto. If compulsory health insurance would really accomplish what its advocates promise, and do this without introducing other and greater evils than those it intends to correct, then it should be adopted. If, on the other hand, after thorough and unprejudiced investigation the plan is found to be of the nature of a political gold brick, then it should be rejected once for all, and we should turn our attention to other and more practical plans for solving the problems at hand.

There are many points from which we might begin the study of our subject, but in our first preliminary survey certain pertinent questions must come to our minds.

In the first place, if the problems of sickness and the economic suffering incident thereto can be

solved as easily as the lay experts in things medical who compose the American Association for Labor Legislation say it can be, why is it that up to the year 1919 not a single State in the Union has adopted compulsory health insurance as a public health policy? It has been in force in Germany for more than thirty years and much of this time we were very busy copying things of German origin. Surely if it brought about the medical millenium it promises it would have produced the good effects in Germany, and some State of our Union would have adopted it many years ago.

Between 1883 and 1914 we have a period of 31 years in which the system was in force in Germany and during this time tens of thousands of American physicians were studying there and absorbing all that was best in German medicine. Thousands of these men are now engaged in public health work throughout this country, and yet to this very day I have not heard one of these men suggest that compulsory health insurance might be a good thing for this country or any single element of the population of this country. In all history of the civilized world I know of no single example where the medical profession has failed to support a measure which in its judgment was calculated to lessen disease or lessen the economic and social hardships produced by disease. If compulsory health insurance is what the lay experts in things medical claim for it, why is it that none of the thousands of American physicians who studied in Germany had or have a good word to say for it? It seems to me that this is a fundamental question, but I will return later to the attitude of the medical profession toward this subject.

In the second place it is worth noting that the so-called experts of the American Association for Labor Legislation have been struggling for at least six and probably ten years in an attempt to formulate a workable draft of a bill. I wish I had time to take up in detail the twenty or thirty differently modified bills which have been introduced into our various State legislatures. Suffice it at present for me to say that I spent much of my spare time for two years trying to devise a practical bill which would accomplish just a small fraction of the results desired and that it was my failure to make any headway in this effort, using the bills of the American Association for Labor Legislation as a basis, which finally led me to the realization of the fact that the whole scheme is fundamentally wrong. Take, for instance, the Davenport Bill, which passed our Senate last winter. It starts out by promising great things as I quoted in my opening paragraph. Almost immediately, however, it excludes from the alleged benefits of the bill all of those persons most needing help, namely, the farm laborers, the domestic servants, the majority of day laborers, the unemployed laborer, the man who works for a small concern having less than eight employees and, listen to this, all those employees for whose benefit an employer, in the judgment of the Industrial Commission, maintains at his own cost and without recourse to insurance, a system, fund, or plan, which guarantees to such employees benefits substantially the same as the benefits they would receive if insured under the provisions of this system. Does anyone here believe that this would mean health insurance in Schenectady? No, it would mean that our larger companies would be forced by the exigencies of the law to return to the long ago discarded plan of the company doctor with all the evils and dissatisfaction attendant thereon.

The company doctor is an old plan. We do not have to repeat history with this experiment which has never been able to survive in this country, except in frontier camps and localities not yet adequately supplied with independent physicians.

A third question which comes up at the very beginning of our study is, Who is behind this movement? None of the parties most interested, namely, the workingman, the employer, or the medical profession, has ever declared in favor of the plan. At least 90 per cent. of the propaganda in its favor can be traced directly to the American Association for Labor Legislation. Concerning the American Association for Labor Legislation I can give you little information. At the 1919 annual convention of the American Federation of Labor, one and only one resolution in regard to compulsory health insurance was passed and it reads as follows (Page 282 of the Report of Proceedings):

Resolution No. 101—By John F. Stevens of Boston, Mass., Central Labor Union; P. Harry Jennings, of Massachusetts State Branch; Martin T. Joyce, of the United Brotherhood of Electrical Workers:

Whereas, During the past few years great efforts have been made to obtain the approval and support of organized labor to a scheme for Social Health Insurance, promoted by persons and organizations who have no affiliation with labor movement; and

Whereas, Owing to the intensive and costly campaign which the promoters of this scheme have carried on during the past two years, at one time seeking to have this legislation adopted in twenty-eight different States, suspicion has been aroused that this scheme is supported by those who, for years, have sought to disrupt and retard the cause of the workers; and

Whereas, The Executive Council in their report, submitted to this convention, have pointed out the necessity of investigating this matter; and

Whereas, We believe that the best interests of the Trade Union Movement demand that an immediate investigation be made of the subject in order that the workers may be authoritatively advised of the benefits or dangers of this scheme and the advisability of supporting or rejecting it; therefore be it

Resolved, That the Executive Council are hereby instructed to make an immediate investigation of this question and to point out its dangers or benefits with their recommendations thereon as soon as possible, and the Executive Council are further instructed to ascertain, if possible, what are the financial resources of the persons and organizations promoting this scheme, and what relation they may have with those interests who are opposed to the best interests of the labor movement; and be it further

Resolved, That the report of the Executive Council on this subject and their recommendations thereon be printed in the *American Federationist* when completed.

At the 1919 convention the Executive Council failed to make a report and suggested that more time be allowed for the investigation.

Concerning the personnel of the American Association for Labor Legislation it is interesting to note that it is composed of a group of lay uplifters, none of whom, as far as I can ascertain, has ever had any objective experience with disease or the effects produced by disease. It is certainly true that any dozen active general practitioners see more of disease and the effects of disease in a week than the entire active membership of the American Association for Labor Legislation does in a year.

These lay experts repeatedly assert that compulsory health insurance is an intelligent attempt to lessen the incidence of disease and ameliorate the sufferings produced thereby. Yet it is worthy of emphasis that to date not a single one of the many public health bodies in this country has actively indorsed the scheme, and yet those bodies are composed of men many of whom have devoted a lifetime to studying the problems of how to reduce sickness and lessen the evil results produced by sickness. Most intelligent attempts to accomplish a great purpose are at least sanctioned by those who know best the problems at hand.

I have mentioned some of the problems which confront us at the very beginning of our study of this subject. I believe that I have at least indicated that there may be some very valid reasons why real experts in things medical are a practically unanimous unit in opposition to the Compulsory Health Insurance Bill. In this State we have a great group of more than 15,000 men who are experts in things medical. Never before have they been found opposed to any measure which in their judgment was calculated to improve the condition of the sick or lessen the sufferings related to sickness, and yet today we find at least 14,500 of these real experts firmly of the opinion that compulsory health insurance is little more than a political gold brick. The reasons for this opinion are many. They apply to almost every feature of the bill, but the time allowed me is limited and I believe that we can ignore statistics and conflicting detail and proceed at once to certain fundamental objections which will at least give an insight into the uselessness of trying to take a project which is hopelessly bad and make something worth while of it.

Compulsory health insurance is unquestionably an attempt at uplift legislation. Now attempts at uplift legislation did not begin in 1919. For centuries lawmakers have been trying to accomplish similar objects, and history very conclusively shows that there are certain fundamental requisites for success of legislation of the type advocated by the compulsory health insurance enthusiasts. First, the law must be fundamentally just. It must not rob Peter to pay Paul. Second, the law must not of itself work directly contrary to those fundamental traits of human character which go to make good citizenship. There are other requisites, but if we study the compulsory health insurance bills of the type advocated by the American Association for Labor Legislation in their relation to these two standards, I believe that we shall be able to get a true measure of the project.

First, let us see if compulsory health insurance of the type advocated by the American Association for Labor Legislation is fundamentally just. The Davenport Bill reads: "The cost of insurance provided by this chapter for employee members shall be borne one-half by the employer and one-half by the employed person, provided that in case the weekly earnings of the employee are less than nine dollars, but more than five dollars, the contribution shall be borne three-quarters by the employer and one-quarter by the employee, and provided that the weekly earnings of the employee are five dollars or less, contributions shall be borne entirely by the employer."

The compulsory health insurance advocates tell us that compelling the employer to pay for health insurance is only a natural step from the principle of the compensation legislation. The compensation legislation, however, only compels industry to pay for the damage done by industry. In order for compulsory health insurance of the Davenport Bill type to give fundamental justice at least approximately, one-half of sickness must be due to industry. In this world of ours it is best to recognize facts as they are and in this case the fact is that industry cannot properly be charged with one one-hundredth of ordinary sickness. In New York City in the four years from 1915-1918 a special effort was made to have all cases of industrial illness reported. During this period the hospitals, private physicians, and the Public Service Commission reported just 322 cases of industrial disease. For the sake of being on the safe side let us suppose that the doctors, the hospital authorities, and the health authorities did not know their business and that there were really 100 times as many cases of industrial diseases as were reported. This will give us 32,200 cases, but during this period there were at least 12,000,000 cases of illness requiring medical attention. This would give us not 50 per cent., but 1/3 of 1 per cent. of disease due to industry.

The meaning of all this is self-evident. The so-called compulsory insurance is not health insurance at all, but only a thinly veiled scheme for forcing charity upon a portion of the community which neither requires nor desires charity. At the same time the people who ordinarily need charity—those chronically ill, the unemployed, the aged, the widows, the orphans—are not provided for at all. In fact they will be much worse off, for the available resources of the community will have been used up in forcing charity upon the man with the job.

Is it any wonder that such wise heads as Gompers, Stone, Hugh Frayne and others want to know the motives behind such legislation? From the days of the Corn Laws of England down to the present time I believe that history will fail to show a single example of a law forcing charity upon employed working men which has not worked to the detriment of the working man and served ultimately to enslave him.

Now let us see how this proposed legislation measures up to the second standard. *Does it tend to encourage those fundamental traits of human character which go to make good citizenship?*

Any law which says on the face of it that industry is responsible for at least one-half of sickness cannot escape the fact that it teaches every man, woman, and child in the State that it is unhealthy to work. Just picture for yourselves the ultimate effect of a law passed in the guise of economic conservation which teaches the doctrine that it is unhealthy to work. Compulsory health insurance in Europe has had two chief effects. It has tended to enslave the workingman and it has tended to increase the number of days lost from real or alleged illness. The statistics on this last phase of the subject are very abundant, but it is not necessary for us to go to Europe for confirmation of the effects

of teaching the doctrine that it is unhealthy to work. For many years before the war the immigrants coming from compulsory health insurance countries presented a peculiar solicitude in regard to the relation between sickness and work that is generally interpreted as a tendency to malinger. I believe, however, that it represented a far more basic psychological state. They had been taught by the laws of their native lands that to work is unhealthy.

In my last paragraph I referred to the fact that compulsory health insurance had tended to enslave the workingman. I wish that I had time to go into this phase of the workings of the law in Europe. It is interesting to note the fact that nearer by, in one of the West Indies, they have a system known as "indenture." Now "indenture" is only a euphonious name for slavery and the "indenture" I refer to is made possible by a highly developed system of health insurance made compulsory by the planters and sugar companies of the island. The "indentured" individual received in the year 1919 a daily wage of approximately 25 cents.

511 State Street.

POSSIBLE DIETARY CAUSES OF RHEUMATISM.

By J. M. W. Kitchen, M.D., M.S.

East Orange, N. J.

In a previous article I dilated on the possibility of plural factors in the causation of rheumatism. Entering into the second year of a knee trouble that is painfully responsive to slight dietary errors on my part, this related matter is of interest to me. It may be of interest to others. An advisory colleague shortly after my trouble started with an articular strain, asked my opinion as to the causative influence of diet on rheumatism—since which time I have not ceased to maintain a reflective attitude to the question. There must be many individuals of sufficient intelligence to have noted the fact of some connection between diet and rheumatic manifestations. Can that connection be satisfactorily explained, scientifically considered?

In view of the fact that dietary errors can be directly connected with many disease conditions as causative factors, there seems to be no adequate reason for rejecting the possibility of such influences in connection with rheumatism. Yet at present there is a widespread belief as to germinal infection being the predominant causative influence—especially, pyorrhea. It would be foolish in this day to ignore the possible influence of microorganisms in connection with almost all disordered bodily conditions; but may we not go too far in this respect? Unquestionably, germs have some influence in causing rheumatism; but to what degree is as yet an open question.

I have not been able to accept the theory that bacteria are likely to initiate a rheumatic condition by a direct attack on a healthy tissue having usual powers of resistance. I may be wrong. Also I cannot ignore the influence of an acquired abnormal habit in keeping up a rheumatic condition, especially if it is of a distinctly local character and one which has a traumatic history. It seems to me that there must be contributary, cooperating causes in the great majority of cases. But one can readily accept the belief that when a disordered state of a tissue has been acquired, invading bacteria may find a favorable place for proliferative growth in that tissue.

Granting that constitutional massive invasion may be the direct cause in acute generalized attacks, may we not lay the principal blame for the invasion to a disorderly condition of the alimentary tract that allows of the transmigration of the germs through a weakened mucosa? The extended area of the alimentary surfaces points to that source of invasion. Add to that invasion an unusual amount of sugar in the blood, there is then a favorable proliferative opportunity for the constitutional development of acids from the growth of bacteria in the general tissues.

It is astonishing that we know positively so little as we do of the disorderly processes of the digestive apparatus, considering that digestion and assimilation are continuously in action as a basis for our existence. Possibly those internists who have made a special and prolonged study of this branch of medicine know more than is generally known; but if they do they have not given their special knowledge the widest publicity. Outside of the printed matter found in all physiological and other text books, what do we know of this matter of normal and abnormal digestive processes?

We know of catarrhal conditions, ulcer, and cancer. We assume that there are hyperemic and anemic conditions. We know of dizziness, dyspeptic discomfort, acid eructations, nausea, gas generation, coated tongue, intestinal stasis, and the horrors of undigested bile impregnated mixtures. We believe in autointoxications of intestinal origin. We know that temperatures of ingested aliments that are in harmony with bodily normal temperatures tend to digestive efficiency, and that wide diversions of alimentary temperatures conduce to upsets of normal alimentary conditions. Cracked ice reduces gastric irritation. Ice cream under some conditions is a valuable form of food. If I eat it in sequence to a full meal, my knee is painfully responsive. There are a thousand and one dietary observations well attested, yet we live in vast practical related ignorance, or without practical applications of our knowledge. In my reading I have noted many questionable statements viewed from a scientific point of view. For example: "Hyperacidity is a *cause* of fermentation." I am willing to stake my reputation on the proposition that fermentation *produces* acidity and that acidity to a large extent controls and restricts fermentation, especially in lactic fluids.

Our alimentary knowledge seems to be somewhat of a jumble of unscientific indefiniteness; though not entirely so.

It is reasonably certain that the laws of health relating to dietetics are those which are least understood, and are those which are most frequently broken; and that such infraction of law is largely responsible for a great average shortening of life in man. We know that the dictates of appetite that have been acquired, more or less shorten the life of every human being, and to a far greater extent than the experiences of hunger for ordinary

reconstructive foods. In view of this fact, is it not remarkable that more study has not been given to the subject, and a wider promulgation given to related hygienic law? The whole world is even very ignorant as to the nature of milk, its preservation, and the proper uses of this, the most elemental of foods. How can it be expected, then, that more complex matters such as the question of incompatibilities of ingested admixed foods can be a part of generally acquired knowledge? We know that this question of incompatability, as well as improper selection of foods in other ways, are comprised in dietary errors. Unintelligent selection as to the physical character of the food needed, is practically a daily occurrence in the lives of most of the race. Unintelligent selection is, of course, very common in meeting the needs of special ages, climatic conditions, and work performed. Man in this connection is apparently suffering from an undeveloped mentality that, while it provides for perception of possible gustatory pleasures, and opportunity for indulgence, falls short of a precautionary development of the power of control to meet and resist the temptations of the table. That undeveloped power of resisting temptation is apparently at the base of much experienced rheumatic misery, as well as of other troubles. Members of the medical profession, at least, have no good excuse for succumbing to such tempting influences because of ignorance. Is it that the immediate presenting influence is more potent than the knowledge stored in the brain? Does not every medical man know what the effects of alcohol, tobacco, tea, and coffee are on the body? Yet why do we subject ourselves to such influences as a matter of personal indulgence?

Every dietitian will admit that practically everybody eats too much as a rule, usually eats uneconomically, and always eats with too wide indulgence in variety of foods consumed. Everyone eats for the pleasure of eating as well as merely to appease hunger. Multimillions live to eat, and relatively few eat to live; and if they do so, make a poor job of their aim. Yet medical men usually know what special foods to recommend to their patients.

In view of the superficial impressions made on the brain of the average medical student during his cramming, undergraduate days, with almost everything else than dietetics, may it not be well to give considerable post-graduate study to this special subject of everyday dietary practices?

The latest acquired knowledge points to the probable fact that animal proteins may frequently be carriers of toxic matters, and especially if they have undergone fermentative decomposition before their consumption. Yet we cannot live without protein in our food, and, as a rule, animal proteins are very much more easily digestible than those of vegetable origin. It seems certain that if freshly killed animal proteins are quickly reduced to liquid assimilable form through complete digestion, such peptic products do not usually effect constitutional damage, even if absorbed in considerable amounts, *if* the excretory functions are sufficiently active. But even the fresh milk of a woman, or of the cow, can transmit toxic principles that have been formed in the body of the producer of the milk. It is largely on this account that I think it advisable so to treat milk as to eliminate as far as possible such possible contaminants. Most adults have become accustomed to the influence of toxic poisons transmitted in their food; but that is no good reason why such toxins should be consumed. Furthermore, if the absorption of toxins is incident to the consumption of the flesh of animals, that circumstance will probably have to be accepted as being coincident to modern civilization. Perhaps our ideals as to civilization should be changed. Possibly we could in time become adpusted to the use of vegetable proteins, including the Boston baked bean, and hence become increasingly bovine in nature. Awaiting that evolutionary step, our attention should be drawn to the possibility of excess protein consumption being a factor in rheumatic manifestations. In considering this phase of the matter, we are brought face to face with the proposition that it may be advisable for man to become less of a meat eater than he is at present.

It has been claimed that the late war was somewhat due to the fact that the ruling classes in Germany have been large meat eaters, and that the advent of peace was encouraged by the fact that the ruled classes ate so many potatoes. No data are at hand indicating the relative incidence of rheumatism in the two classes.

Excessive consumption of sugar and starches, as well as of meat, is charged as being a dietary cause of rheumatism. Perhaps human nature would be advantageously modified if man became more vegetarian in his diet, but the trouble seems to be more a question of quantity and quality. It is certain that a large part of the food we eat is not changed into tissue or manufactured energy. The excess consumed simply interferes with our best health status.

What the effect of the consumption of admixed food incompatibles may be, is practically unknown. Possibly the gastric tissues experience a sense of outrage when confronted with some of man's ingested food conglomerations. The gastric embarrassment of the French has frequently sufficient causation.

It will be generally admitted that digestive disorders have a great deal to do with the production of various other disordered conditions, and that through the dietary correction of such conditions the auxiliary disorders are alleviated or eliminated. But there does not seem to have been any systematic grouping of correlated knowledge in a way that allows of individual application of that knowledge.

Consider, for instance, the question of "hyperacidity," which, correctly or not, has been charged with being the causative factor of all sorts of bodily disorders, including rheumatism. Unquestionably there are various etiological combinations which produce rheumatism as a sequence to digestive disorders, and probably, also to noninflammatory conditions in which unusual amounts of acids are formed due to too great an amount of food ingested, lack of comminution, really difficult digestibility of the food, and acid-inducing character of the food. Defective digestive activity is a usual sequence to neglect in taking exercise; and defective elimination follows inadequate oxidation of food. Under such conditions the constitutional accumulation of acids and other irritating concentrates may occur. While hyperacidity may result from gastric irritation due to too great consump-

tion of proteins of any physical character, it will certainly result from ingestion of moderate amounts of proteins of unfavorable physical character. Hashed meats may be quickly digested, when the same food bolted in larger particles will be followed by excessive gastric stimulation. A poached egg may be irritative when a finely comminuted hard boiled egg will cause no distress. A thick, gluey preparation of oatmeal may be irritating when the same amount will not be irritating if prepared in the form of a thin gruel. Many concentrated foods will induce irritating hyperacidity that would not have occurred if the same food had been sufficiently dilated with dry or liquid neutrals. Frequently I have found that an acidulous gastric condition that would have been felt in my knee has been rendered harmless by a sufficient ingestion of water.

Many persons who habitually consume too much protein escape trouble by coincidently ingesting an alkaline corrective. Whether excessive consumption of proteins that in one or another way pass through the stomach without unduly stimulating that organ, may result in constitutional irritation from putrefactive decomposition of that excess in its travel through the intestine, is a cause of rheumatism, cannot be determined in our present state of knowledge. Possibly, unusual absorption of volatile, diffusive, putrefactive, decomposition products may indirectly be a cause through depressive constitutional action. I have not found that a considerable ingestion of milk, which is certainly highly nitrogenous, has any particular irritating effect. Possibly that may be due to the presence in fresh milk of more or less of an antifermentative constituent. It has been found that fresh unfermented milk is equally effective with the fermented article in preventing intestinal putrefactive decompositions.

It is claimed, and with probable justice, that excessive consumption of starches induces hyperacidity. This possibility can be reasonably explained by the fact that the starches becoming dextrinized furnish a favorable nutrient for the acid-forming bacteria that are more or less present in the alimentary canal.

It is reasonable to assume that unusual accumulation of sugar constituents in the general tissues may undergo acid-forming conversion through the action of acid-forming germs that may have passed from the intestine into the general circulation, especially if there is a coincident disordered condition of the alimentary mucosa.

It seems safe to accept the proposition that proteins that cause excessive gastric irritation, and an excess consumption of starches and sugars, are at least somewhat causative of rheumatic conditions; but I am inclined to think that defective elimination of excretory organic matters is more often a direct source of irritation to tissues particularly subject to rheumatism than specially potent irritants developed in the alimentary canal. In considering this subject we should bear in mind that irritating matters produced in the alimentary canal may or may not be a constitutional irritating factor, according to the susceptibility of the affected tissue. A tissue disorganized by a traumatism may be susceptible when one in a normal condition would not be susceptible. Furthermore, certain individuals, as in the carnivora, are accumstomed to a state of constitutional acidity. We should not forget that acidulous conditions that are harmful under some circumstances are impotent under other conditions.

An inquiry of the present character does not lead far toward scientific conclusions; but practically, it seems to lead to an acknowledgment of the soundness of various time honored precepts, such as "moderation in all things"; comminution of the food is desirable; don't bolt it; don't eat much expensive meat and acidulous fruits; limit yourself in starches and sugars; finish your meals hungry. If one must stuff, do it with foods that contain a large proportion of unfermentable cellulose and relatively small amounts of constructive and energy-making constituents. All of which is easy to say; but few will give heed to such excerpts of wisdom. Hence the profession may expect a reasonable patronage from rheumatic patients in the future.

Will future generations pay their family physicians to be kept free from rheumatism? Until they see the wisdom of paying for preventive treatment, they will have to suffer more than they should. Perhaps the greatest difficulty to overcome in prevention is because of dilatation of the alimentary passages acquired during many years of overeating. When that condition exists, the victim is uncomfortable unless he fills the cavity at his meals; and this always results in those troubles that follow unwise indulgence of desire. In cure, the greatest difficulty to meet is overcoming an acquired chronic bad habit of localized inflammatory action. Sometimes this is an incurable habit. The writer speaks feelingly. In the treatment of his own case, he has experienced difficulty in overcoming the dietary habits of a lifetime, and hence suffers; but he also, with the aid of local bandaging, massage and use of crutches, has maintained general health, and a reasonable amount of life's activities.

My latest pertinent conclusion is that foods which produce disordered conditions of the alimentary surfaces are causes of rheumatism.

MENTAL DISEASES.

By H. LAVESON, M.D.,

NEW YORK.

(*Concluded from page* 722.)

GENERAL PARALYSIS.

Synonyms.—Dementia paralytica; paralytic insanity. General paralysis is an organic disease of the cortical part of the brain, characterized by progression, by the combined presence of mental and motor symptoms, the former always including mental enfeeblement and mental facility, and often delusions of grandeur and ideas of morbid expansion or self-satisfaction; the motor deficiencies always including a peculiar articulation of words, and always passing through the stages of fibrillar convulsion, incoordination, paresis and paralysis; the diseased process spreading to the whole of the nerve tissues in the body; being as yet incurable and fatal in a few years.

The disease, for convenience's sake, has been divided into three stages. In typical cases the first of these is that of fibrillar tremblings and slight

incoordination of the muscles of speech and facial expression, and of mental exaltation, with excitement; the second that of muscular incoordination and paresis with mental enfeeblement, and the third that of advanced paresis, with little power of progression, almost inarticulate speech, and at last paralysis with mental extinction.

Let us look at a typical case in the first stage of the disease: For a few months the patient's friends have noticed that he "has not been the same." Six months ago he was not in good spirits, and complained of flying pains in the head; then he was a little forgetful, wanting in application to his work, restless, doing some unaccountable things in business, *e.g.* forgetting to claim money due to him. He was irritable at home, a thing unusual with him. A month ago he began to express an exaggerated sense of well-being, saying he never was so well in his life, that his strength was "something wonderful." He could not settle down to his daily work, his natural high opinion of himself was more openly expressed to comparative strangers, one of whom remarked, after seeing him: "What a conceited fool that man is!" This state went on without any other absolute signs of insanity and without awakening the suspicions of his friends that he was mentally wrong—that is the last thing thought of—until one morning he announced to his wife that he had the day before purchased several hundred dollars' worth of silver plate, and had ordered the coat of arms, with his name in full, to be engraved on each article. He added that he had lots of money, and a scheme through which in a week he would be worth many hundreds of thousands of pounds.

On inquiry it was found that he had ordered the plate; but the jeweler, being a man of sense and principle, having noticed some little thing in his manner, had not taken any steps to execute the order till he made some inquiries. He had in his pocket four gold pencil cases which he said he was to give away as presents to people to whom he was under no obligation, and did not know very well. The restlessness by day and night increased; there was constant talking, almost complete sleeplessness; the boastfulness became in three or four days exaggerated delusions. He said he could lift a thousand pounds, that he was the best rider, swimmer, and jumper in the world. He wanted to buy every farmer's horse he met on the road, never offering less than a hundred dollars for any animal, and at once bidding another hundred dollars if the first offer was jocularly refused. He wrote quantities of letters to all his friends, to all the officials in the district, offering his services to make their fortunes, and asking them to dinner. The early visible peculiarity of the writing was the omission of many single words. In a few more days he was maniacal, and so impatient of contradiction that he struck his wife; yet through all this he was in some respects facile and easily managed. He therefore had to be brought to the asylum a week ago.

Let us look at him now. He comes into the room with a quick step. His attitudes and gestures follow and accentuate his speech. He talks rather quickly, and has the least slurring toward the end of long sentences and in articulating long and difficult words with many oft-repeated consonants. "Round about the rugged rock the ragged rascal ran" was got through fairly well the first time, but at the second attempt the "ragged rascal" got into a sort of inarticulate slur. This is accomplished by fibrillar twitching in the small muscles of the lips and around the eyes, as if a sudden electric current had set these quivering. As he breaks into a smile this is very apt to happen. His tongue quivers in lines on its surface, single strands of muscles being affected. His pupils are contracted, irregular in line, and the right is distinctly larger than the left, the latter being quite insensitive to light. Sometimes it is one pupil and sometimes the other that is small and insensitive or large and insensitive in different cases. The expression of his eyes is feverish and strange. His skin is moist and feels hot. He was easily led off from one subject to another; this facility is one of the most characteristic of all the symptoms present in all stages of the disease. He is irritable on contradiction, and resents thwarting, especially if it is done suddenly. General paretics at this stage are sometimes very dangerous, from their absolute fearlessness of consequences.

Let us now see a typical case in the second stage of the disease: There is want of facial expression, his face looks fat, heavy, and dull, as if the expression had been wiped out of it, and this is particularly noticed when he speaks. There are no movements of the features corresponding with the emotions he is experiencing. There is heavy flabbiness about him. He expresses few wants, says he is quite well, and that he can walk, work, sing, or do business as well as he ever did, none of which is true, for he is very shaky on his legs, cannot walk a mile, his handwriting is tremulous, and he has no initiative mental power, no spontaneity, and no power of volition. He does not now obtrude his delusions, but when asked he still says in a facile way he is rich and strong. His pupils are widely dilated, and the left more so than the right; his tendon reflexes function dull, too; his power of swallowing is a little impaired. His speech is very markedly affected now, and the tone of his voice is quite changed. He cannot say "Round about the rugged rock the ragged rascal ran" at all, nor such test words as "royal artillery," "hippopotamus." There are tremblings about his face as he speaks, but they consist of the incoordination of whole groups of facial and articulatory muscles. The dorsum of his tongue presents a general undulatory surface when put out. He cannot turn around quickly without risk of falling, or stand on one leg; he straddles a little in walking, is apt to stumble over small obstacles, and the effort of a long walk so exhausts the energizing power of his muscles that he gets almost paralyzed and is then unable to walk at all. There is no vigor in any muscular movement he performs. His urine dribbles away.

In the third stage he is paralyzed, he can neither walk nor stand steadily. He cannot write, and his mental state is that of a happy lethargy. When asked if he has a million of money his facial muscles begin to act in an incoordinated way, his eyelids half shutting, his mouth being drawn out, the lips moving spasmodically, like a patient going into an epileptic fit; the whole effort being that of a contorted imitation of a smile, accompanied by a slow, prolonged and jerky "Y-a-a-a," which is all that he can articulate for "yes." But he looks as if

his subjective condition was one of perfect happiness. He asks for nothing, he complains of nothing; he is noisy at night often, but it is in an automatic way. All his food has to be liquid or minced, for he would bolt it in solid masses, and choke.

Pathological Appearances in the Brain.—The encasings and supports of the organs are all found to be affected, and the longer the case has lasted the more marked are the changes met with. The bone of the calvarium is denser and harder, in many cases the diploë being obliterated, and in many others there is distinct layering and deposit of new bone on the inside of the inner table of the skull cap, this being usually confined to the frontal and parietal bones. The dura mater is thickened, adheres more or less to the bone, and frequently leaves shreds attached to the bone. In a number of cases we find, under the dura mater, and attached to it, lying between it and the arachnoid, a new substance of a morbid and peculiar kind, commonly called a false membrane. There is a general hyaline degeneration of the vessels and their perivascular canals which leads to the obliteration of both. While the vessels are undergoing this morbid change small hemorrhages frequently occur from them. Their obliteration is followed by the formation of new capillaries, which are doubtless required to maintain the nutrition of the fibrous tissue. From these new vessels, the formation of which is necessarily accompanied by the development of a certain amount of granulation tissue, further minute hemorrhages occur. The extravasated blood becomes the basis of more granulation tissue. These changes are at first subendothelial, but the extending granulation tissue soon breaks its way through this barrier and a membrane becomes developed. This is the so-called pachymeningitis hemorrhagica interna of the Germans, a misleading name, for it is not the result of inflammation at all. The arachnoid is immensely thickened, and is also matted with white fibrous-looking bands. The pia mater is thickened, vascular, and tough to an enormous extent. The convolutions are atrophied, especially over the vertex of the anterior and middle lobes and in some localized places elsewhere. When the pia mater is removed from the convolutions it is found to adhere to and raise up portions of the outer layer of the gray substance on the ridges of the convolutions. The convolutions from which those patches have been removed look eroded. It is by far most frequently confined to the vertex and the anterior and middle lobes, to the convolutions of the hemispheres lying in contact with each other above, below, and in front of the anterior part of the corpus callosum, and to the gyri around the olfactory bulbs at the base. In some cases we find this adhesion of the pia mater at the base, over the orbital convolutions and the middle lobes. On opening the ventricles they are nearly always found enlarged, but the most striking peculiarity is that their normally delicate epithelial linings are toughened and roughened in an extraordinary degree. Their surfaces look in the less marked cases like frosted glass, in the more marked cases they are granular and even minutely nodular, feeling rough to the touch. This condition is usually most marked in the floor of the fourth ventricle, and the covering of the calamus scriptorius is always a grayish, gelatinous-looking but really tough membrane. The single normal layer of delicate epithelium has become enormously hypertrophied, and in addition the neuroglia underneath it, and for a short distance down into the nerve fibers or cells, has become hypertrophied in limited areas, throwing itself up in masses, thus constituting the bulk of the granulation.

SYPHILITIC INSANITY.

The mental as well as the bodily symptoms of brain syphilis have attracted much attention of late years. It is a large subject because the functions affected are numerous; an obscure subject, because the effects of the disease are often very slight and slow in development and are multifarious in kind; and is an interesting subject to the alienist, because it is a disease in which the mental and bodily symptoms can after death be often directly connected with the pathological lesions present and because in some cases the resources of therapeutics are most powerful and direct in curing the disease.

There is no doubt that a hereditary predisposition toward the neuroses determines the effects of the poison toward the brain. In addition, injury to the brain, previous disease, veneral excesses, overstudy, mental anxety or worry, and even fright may all act as determining causes of brain syphilis. In nearly seventy per cent of all cases there has been complaint first of headache, chiefly of a nocturnal character, often of great severity and unrelieved by ordinary means; then of sleeplessness partly owing to the continual pain, and lastly to vertigo. These constitute in the majority of instances the prodromal indications. There is a feeling of physical inability to accomplish work of any kind, then incomplete ptoses or occulo-motor paralysis. There is nearly always a stage of irritability lasting for days, usually several weeks, and occasionally amounting to maniacal excitement, after which the patient may be for a time depressed. By this time a noticeable degree of mental reduction has been reached, the finer details of life being forgotten and neglected. Rarely are there more than transient delusions, some fanciful others approaching expansive forms. The delusions of to-day may be entirely lost on the morrow and never recur.

Unless the disease is arrested at this stage there now begins a series of phenomena of grave import. The patient may waken in the morning with a paresis of the arm, leg, or face, which, during the succeeding days, slowly recedes until complete use of the part is regained. Epileptiform seizures—convulsions followed by transient paresis of one or more extremities—is a very frequent occurrence. Convulsions now begin, frequently limited at first to one extremity, then becoming more widespread, and finally universal if the seizures be prolonged. The general mental condition after a time becomes exceedingly degraded, the patient being apathetic, somnolent and untidy.

The pathological substratum of syphilitic insanity consists in:

1. Syphilitic tumors, gummata, or syphilomata;

2. Specific disease of the brain arteries. The basal ganglia are softened and congested in spots. An examination of the arteries of the brain shows

a hypertrophy of all the coats, causing obliterations of the lumen in places, irregular contractions and nodulated thickenings. Every form of irregular local arteritis is found, all the vessels being more or less affected, but especially the branches of the middle and anterior cerebral arteries.

The microscopic appearances are very striking. The arteries in the pons are thickened, the muscular coats being hypertrophied to an enormous extent, the outer coat being also much thickened, and in and around the coat there is a molecular deposit containing granular masses, this deposit in many instances filling up the perivascular space. At some parts the vessels are potent, at others completely occluded and the lumen absent.

Treatment.—The treatment of syphilitic psychoses does not differ from other luetic affections. Mercurial preparations are the chief reliance at all stages, either in the form of inunctions of blue ointment or oleate of mercury. The inunctions should be used frequently and not in too small amount. Better salivation with cure than a progression of the disease to dementia. The internal administration of the various salts of hydrargyrum should not be neglected, either during or after inunctions. I prefer to combine the bichloride with iodide of potassium, gradually raising the quantity of the last named salt to high doses, believing that it has some effect in promoting the resorption of the products of inflammation around the vessels. Iodides alone should be given only in tertiary syphilis; even then it is better to add a small quantity of the bichloride to it. Tonics containing iron, phosphates and other tissue-builders are indispensable in syphilis. Diet must never be neglected. It should be full, but not too stimulating, and should consist mainly of eggs and milk, vegetables and wheat meal in all forms. The newer remedies, such as salvarsan and neosalvarsan by subcutaneous or intravenous method, may be tried.

SENILE DEMENTIA.

Senile dementia may occur in a simple demented form with amnesia, enfeeblement of the critical faculty, and changes in the emotional and moral character as its most prominent symptoms. Melancholic depression is common in such cases. More often, however, are those in which confusional attacks from time to time under the course of the disease may appear. Special mention must be made of the precocious forms of cerebral arteriosclerosis, which have been designated presenile or Alzheimer's disease. They are so closely allied to senile dementia by intermediate grades and varieties that they ought not to be regarded as separate from it. In these presenile forms of cerebral arteriosclerosis the most important symptoms are those indicating a focal lesion. As a rule they are slowly established, but they may also arise suddenly with, for example, an apoplectiform attack, hemiplegia and hemiparesis. On the mental side there is to be noticed a gradually increasing enfeeblement of memory, reasoning power, with euphasia, or hypochondriacal depressions. Melancholy is the most common of the psychosis of old age. Cerebral arteriosclerosis is always accompanied, even in its incipient stages, by various subjective phenomena, such as headache, often slight but constant, a feeling of faintness, giddiness, ringing in the ears, the irritability of weakness and insomnia. These are in many cases the prodromal symptoms of senile dementia, which subsequently develop in a slow and progressive manner.

In senile dementia, independently of the peripheral changes which injure the sensory organs, there is a weakening of perception. It is delayed or more or less inaccurate and incomplete because the capacity for active attention is diminished and the memory of things perceived is transient. It is particularly during conversation that this defect assumes a prominent character. The memory always presents large blanks. The patients can recollect well the more important events of their childhood and youth, but they cannot recall what they did or heard the day before or even an hour or a few minutes previously. He may forget the name of the person with whom he was talking as he rambles on, and may ask it several times in a few minutes. From this defectiveness of memory there naturally arises a failure to appreciate the passage of time, the patients cannot tell the day, or the month, and may even mistake the year. In this way they lose—and it is a characteristic phenomenon—the idea of their own eye. Apart from the state of restlessness, peevishness, and irritability, which is nearly always present in such cases, the enfeeblement of perception and memory directly gives rise, on its own account, to emotional disturbances and delusional ideas.

INFECTIOUS AND INTOXICATION PSYCHOSES.

These may be conveniently considered under the following headings:

A. The so-called infectious or fever deliria. This category includes all forms of mental aberration associated with febrile diseases and not forming an integral part of other psychoses.

B. The acute or collapse delirium.

C. The subacute delirious or confusional states variously described as acute hallucinosis, acute confusional insanity, and finally Korsakow's symptom complex.

A. The Fever Deliria.—Mental aberration of varying degrees of intensity and of length of duration has been reported in connection with practically all the febrile diseases. The frequency of these psychic manifestations depends upon a number of conditions, such as the nature of the disease, the severity of the epidemic, the time of life at which the individual is affected. Women who suffer from an acute infectious disease are somewhat more prone to show signs of alienation than are men, and the greatest number of cases are noted in both sexes during the prime of life. The dominant symptoms are:

1. Impaired associative activity.
2. Disorientation.
3. Psychomotor excitement.
4. Fallacious sense perceptions developing delusions.
5. Anxious affective states.

B. Acute Deliria.—The great majority of delirious states, since they develop during the height of the disease, belong to this second subdivision. This is particularly true in regard to typhoid fever, pneumonia, influenza, acute rheumatism, meningitis, and

the various exenthemata. The symptoms may not differ essentially from those already described as belonging to the prefebrile deliria, except that in the majority of cases the onset is more gradual. There is nearly always considerable interference with the transmission of sensory impulses, psychic anesthesias, paresthesias, or hyperesthesias sometimes appearing, generally associated with hallucinations and delusions. Consciousness is almost never unclouded. The degree of motor restlessness varies greatly in different individuals, sometimes being so intense that the patient can be restrained only with the greatest difficulty, while in other instances it is limited to spasmodic twitchings or incoordinated choreiform-like movements of the extremities. At times there develop twitchings of the facial muscles and some interference with the muscles of speech, more rarely with those of deglutition. Hallucinations and delusions, particularly those of a dream-like character, begin to make their appearance. There is an exaggerated tendency to talk and a sensory flight of ideas.

C. Postfebrile Psychoses.—For the sake of convenience these may be divided into two groups:

1. Those occurring coincidently with or soon after the subsidence of the temperature;

2. Those developing more slowly and after a longer lapse of time.

After the drop in temperature has occurred or during the period of convalescence acute delirious or confusional conditions may develop. At present it is the general consensus of opinion that the pathological changes which occur in the central nervous system as the result of elevations of the bodily temperature are to be regarded as the results of autointoxication.

Korsakoff's Syndrome; Polyneuritic Psychosis.—Mention occurs in the literature, as early as the middle of the last century, of the mental disturbances met with in alcoholics with accompanying lesions in the peripheral nerves. In this country the subject was referred to by Mills in 1886 and by M. Allen Starr in 1887, but this syndrome was first described in detail by Korsakoff, whose name is now commonly associated with this clinical picture.

The psychic aberration may be briefly summarized as consisting in defects in associative memory, confusion with a marked tendency to confabulate and indulge in pseudo-reminiscences, hallucinations, and delusions, whose character will be presently described, and marked fluctuation in the affective life. In many alcoholic cases the syndrome bears a striking resemblance to certain forms of delirium tremens, and for this reason, as well as because alcohol was a causative factor in so many cases. In the instances which frequently come under observation, where there is a marked disturbance in the functions of the peripheral nerves, we meet with anesthesias, paresthesias, or hyperesthesias, more or less directly referred to the distribution of the peripheral nerves, at times an ataxic incoordination, an atrophy of muscles. These neuritic symptoms may or may not precede the development of the mental symptoms.

In almost all of the cases there is a prodromal period during which the patients show signs of some mental aberration, irritability, at times sleeplessness, at other times a marked drowsiness or even stupor from which they are aroused only with the greatest difficulty. After the lapse of a varying interval of time, the characteristic delirium makes its appearance. As a rule, memory for the immediate past is markedly defective, although the individual may retain a relative knowledge of the earlier periods of his life. The tendency to confabulate and indulge in pseudo-reminiscences is extraordinary and is one of the most characteristic features in the majority of the cases. Such patients will frequently narrate long tales having every semblance of truth and yet upon investigation it will be found that they have no substantiation in fact. The hallucinations and delusions in a measure resemble those present in other toxic states. Those connected with the visual, tactile and more rarely the auditory sense are met with.

IDIOCY AND IMBECILITY.

The word idiot is derived from the Greek "a private person," peculiar, *i. e.*, a person devoid of understanding from birth; incapable of holding communication with another, therefore set apart alone.

The term imbecility is taken from the Latin *Imbecilis—im* and *bacillum* as needing a staff, wanting strength of mind, "weak and feeble," expressive of a certain degree of intelligence, but unstable, incapable, irresponsible.

The idiot intelligently sees nothing, feels nothing, hears nothing, and knows nothing. He simply lives alone—the solitary one. The imbecile, on the other hand, is able to see, to understand and to discriminate in greater or less degree. Spitzka says: "Imbecility is a deficiency of the brain, with permanent impairment of the intellectual faculties," whereas, "Insanity is a mental condition, the result of brain disease, affecting the integrity of the mind, characterized by intellectual or emotional disorder."

There are different degrees of idiocy: there is the absolute idiot—the importunate creature who has hearing, but seems not to see; who never learns to talk; who cannot put on his own clothes or feed himself or do the simplest thing. There is the imbecile who cannot take care of himself at all, but can do pretty well under the direction of others. There is the simpleton who thinks he is a man, and who hangs on the skirts of society, the victim of some and the butt of others.

Diagnosis.—The child who enters life through the portals of undue suffering, or who comes freighted with a pernicious heredity, will perhaps be found either extremely quiet and apathetic, or fretful and excitable, the eyes staring and vacant or rolling aimlessly may see without looking, or as in cases of photophobia be enormously hidden from view. The child is slow in learning to sit, to hold up its head, to use its hands. He is backward in noticing objects, in responding to caresses, and the mother, to him, is often no more than any other nurse; or he may be restless, nervous, irritable, crying and refusing to be pacified. Slovering is common, due to the hyperemic conditions of the salivary glands. The hearing is imperfect, speech is delayed often beyond the seventh year, and articulation is apt to be defective. Lack of coordination and reflex muscular movement is seen in the halting, slouching gait. There are cranial deviation from the normal —asymetric, flattened or seemingly pressed out of shape; the head abnormally small—microcephalic, or

abnormally large—hydrocephalic. The ears deformed, enlarged, twisted, or rudimentary; the lobules frequently defective, adherent, or absent, pinnæ and helices faulty; tubercles of Darwin often; the ears may be implanted further back than normal. The nose rudimentary, enlarged, flattened or the alæ are very wide. The mouth is large and coarse, often in lower grades, open, and drooling (sialarrhea); the lips are either thick, frequently sore at the corners; the palate misshapen, narrow and vaulted like an inverted V, the gums swollen and spongy; the teeth decayed. In both idiocy and imbecility the sexual desires are exaggerated in the various grades in proportion to the predominant power of the mere animal over the psychic forces. The profound idiot, apathetic, can give no expression to his wants by either speech or motion; he lies simply a breathing mass of helplessness.

BORDERLAND CASES.

Neurasthenia.—Neurasthenia, according to Freud, resolves itself into two typical clinical pictures: into so-called "true neurasthenia" and into anxiety neurosis, which forms not only have a specific etiology but can also be sharply differentiated clinically. Under neurasthenia is meant those frequent symptom-complexes of pressure in the head, spinal irritation, dyspepsia with flatulence and constipation, paresthesias, diminished potency as well as a prevailing emotional depression. This clinical picture corresponds to the specific cause of excessiveness of masturbation or frequent pollutions, or, better expressed: neurasthenia may in every case be traced back to a condition of the nervous system which has been acquired through excessive masturbation or arisen spontaneously from frequent pollutions.

A boy who practises onanism excessively at puberty usually remains without control, and when warned by companions or one of those dangerous popular scientific books, he is changed into a hypochondriac who interprets the symptoms of his neurasthenia as the premonitory signs of a softening of the brain resulting from his self-pollution. Falling into anxiety and depression, he suddenly gives up his masturbation and often begins to suffer from frequent pollutions. The outlet provided for the discharge of the sexual product by the act of masturbation does not correspond to the complicated spinal reflex act with its psychic preliminaries as provided by normal coitus. From this abuse arises also the widespread symptom of ejaculation præcox, which betrays years afterward the youth who had been greatly given to onanism with phantasies. Such men are not in condition to give the woman the normal outlet for her excitement and gratification of coitus.

The chief service which the wise physician can render to the neurasthenic lies in the prophylaxis. If excessive masturbation in youth is the cause of neurasthenia, then the prevention of the same in both sexes deserves more attention than it has yet received. Until now the weighty question of masturbation could, however, receive no decisive answer because, on the one hand, the existence of masturbation in the suckling and child has not been sufficiently recognized, and no agreement has been reached between the disparate medical views regarding the onanism of puberty and later life. The purely autocratic masturbation in the littlest children may seldom and only in excessive cases demand the interference of the tutor, not to mention the physician. Childish onanism around the third or fourth or fifth years must within certain limits be considered a normal phenomenon. Further, this is normally soon replaced by the so-called latent period. If this does not occur or if the practice becomes excessive, then it must be checked. Nevertheless, terrifying and gruff prohibition is to be avoided; much more can be accomplished by gentler methods. Often in the neurosis which breaks out later there appears the anxious hallucination of parental prohibition; through the quite customary threat of cutting off the penis. A further psychic trauma may be inflicted which is frequently followed by lasting and pernicious results. It must be emphasized at the beginning that this onanism cannot be entirely avoided, because in our civilized social organization too great an interval has been interposed between the awakening of the sexual instinct and the possibility of its regular gratification. There is thus the necessity of allowing this mode of gratification up to a certain degree, that is within moderate limits and with quieting explanations; it can then be observed that this happens without real injury. In general, the injuriousness especially of excessive masturbation is not to be doubted in the least even if part of the medical profession is not inclined to share the hypochondriacal exaggerations of many nervous patients who would trace back all evil to their self-gratification.

The injuriousness begins in the somatic field in that onanism gives occasion to excessive sexual activity, does not take into consideration all the psychological source of excitement affords inadequate relief and diminishes potency. More important are the injuries in the mental field. The easy attainability of the goal of gratification in masturbation weakens the individual for the strife of life which can no longer be undertaken with the necessary display of energy. Through his turning away from society the masturbator becomes antisocial and betrays the result of his vain strife against passion in a number of other characteristics, as weak will power, doubt of the possibility of accomplishment and similar self-reproaches. Thus there seems to be a kind of mental type for him who has misused onanism.

Psychasthenia.—Psychasthenia may be defined as an affection of the nervous system in which the psychic influence predominates, those cases which are more or less amenable to psychotherapy and whose source of trouble is often psychic rather than somatic in origin.

Etiology.—It occurs most frequently in hereditarily predisposed individuals, overwork, stress and strain, and intoxication serve to develop and accentuate this disease. Fatigue and exhaustion are most destructive to the nervous system and are undoubtedly a cause of psychasthenia. In order to produce the disease it is necessary that there should be a particularly close affinity between the event playing the part of provoking agent and the natural or temporal disposition. The true cause is therefore to be found in this native weakness of the mentality which allows commonplace factors to precipitate the individual into an abnormal state.

Symptoms.—The disease usually makes its appearance at or around puberty. The child is spoken of as delicate, nervous and timid. They are all introspective and with the workings of the mental machinery and the physical processes with an eagle eye of a trained detective. They watch the minutest detail of their daily work, only to criticise their best efforts and worry over the results. They are incessantly spying upon themselves. They look at everything with a magnifying glass, the slightest event becomes a catastrophe. Their slumber is more or less disturbed by nightmares and other vivid dreams, all of which are largely born of the overanxious and apprehensive watchfulness during their waking hours. The psychasthenic is usually highly impressionable, more or less timid, hesitating, lacking in initiative, usually a dreamer, often overscrupulous, unfailingly exaggerating the importance of his personal shortcomings, all the while extremely irritable, very changeable in humor and more or less despondent. It is easy to detect their lack of logic and the mental genesis of a host of autosuggestions which rule them.

At the very outset we have the symptom of ready mental exhaustion—of marked diminution in the capacity for sustained intellectual effort. He is incapable of long-continued mental effort. The attempt to do mental work brings on more or less rapidly the symptoms of fatigue. A certain task may be properly begun, but soon the patient experiences difficulty in keeping his attention fixed upon it. If the effort be persisted in this difficulty it increases until at last, instead of clear and distinct ideas, vague and confused impressions alone are received. At the same time painful sensations are apt to arise, a sense of tension about the head, headache and even giddiness. In a well-developed case of psychasthenia the difficulty of concentrating the attention may be so great as to lead to an habitual state of distraction and inattention, associated with a more or less marked dislike for mental effort. Added to the above symptoms we have those of a diminished inhibition. The most trifling causes often excite and anger the psychasthenic patient. He is irritable to a degree. He is also apt to be unusually sensitive and often feels hurt by fancied neglect or oversight on the part of relatives or friends. He experiences changes in the emotions more readily than in health. Totally inadequate causes may provoke marked depression, and at other times laughter. His emotional equilibrium is readily disturbed. There is a tendency to introspection noticeable; in a large proportion of cases the patient is apt to dwell upon his symptoms and to be constantly alive in his illness.

Treatment.—One of the first requisites for treatment is that the physician should possess the entire confidence of the patient and her friends. There is probably no disease which a medical man has to treat which makes so many demands upon his firmness, self-control and ingenuity as psychasthenia. He must be able to sympathize with the feelings of the patient in order to command her confidence, but if his sympathy falls into false sentiments or into the slightest exaggeration of manner he will only be administering to the morbid craving for sympathy which is at the root of the disease, while, on the other hand, the slightest attempt to laugh down the patient's fancies may be fatal to success. Earnestness of purpose, determination, and fertility of resource are all called into requisition in the treatment of psychasthenia.

Breuer and Freud maintain that the symptoms of the psychoneuroses have their origin in a psychic trauma, which at the time of its incidence is accompanied by an emotion. The persistence or disappearance of the memory of such an event depends upon several factors. Above all, it is important whether the individual reacted energetically at the time or not. Under a reaction are comprehended the entire series of voluntary and involuntary reflexes by which the emotions are commonly discharged, from weeping to an act of revenge. If such a reaction takes place in sufficient measure the emotion in great part disappears. If the reaction be suppressed, the emotion remains attached to or associated with the memory. The treatment, therefore, consists in the ability of the physician successfully to arouse in the patient the memory of the event which was causal to the development of the symptom, along with the accompanying emotion.

Hysteria.—Hysteria is a pathological state manifested by disorders which it is possible to reproduce exactly by suggestion and can be made to disappear by the influence of persuasion.

Etiology.—Hereditary predisposition exerts a powerful influence in the production of hysteria. It occurs with preponderating frequency although by no means exclusively in the female sex. All causes which lower the nutrition of the nervous system, as hemorrhages, insufficient nourishment, impaired digestion, and anemia predispose to hysteria. Exhaustion from overwork when combined with anxiety, as in the case of those who have to nurse sick relatives, is one of the most fruitful causes of the disease. The depressing passions, as fear, anxiety, jealousy, and remorse, frequently induce hysteria.

Symptoms.—1. Sensory disturbances: (*a*) Hyperesthesia in some form or another is seldom absent during the course of hysteria. The patients complain of neuralgic pains in various parts of the body in the absence of any recognizable cause. The senses of touch and temperature are sometimes increased in the acuteness. Cutaneous hyperalgesia is sometimes widely diffused, so that the slightest movement of the patient causes discomfort. They suffer greatly from cardialgia, and, when it is associated with persisting vomiting, the symptoms may be mistaken for those of perforating ulcer of the stomach.

(*b*) *Anesthesia.*—Diminution or complete loss of sensibility is a very frequent symptom of hysteria. It may exist over a large portion of the surface of the body, and may implicate the muscles and deeper tissues as well as the nerves of special sense. In the majority of cases sensibility to pain is alone altered, while the other forms of cutaneous sensibility to pain is alone altered, while the other forms of cutaneous sensibility remain normal. Cutaneous anesthesia is often limited to certain circumscribed portions of the surface of the trunk and extremities; it may be observed in the region of distribution of one or more nerve trunks, be limited to one or more extremities or be accurately confined to half the body.

2. Motor Disturbance: (*a*) Spasms, either tonic or clonic may occur in group of muscles of the head, trunk, and extremities. Spasmodic closure of the glottis may produce alarming dyspnea, and the patients are liable to attacks of convulsive laughter and weeping which often arise apparently in the absence of any emotional disturbance. During hysterical attacks loud screams are commonly emitted. Eructations, barhorygmi, and griping pains may also be caused by irregular peristaltic movements of various portions of the digestive canal.

(*b*) Paralyses: Partial or complete loss of muscular power is a frequent symptom. The loss of motor power may begin with mere weakness and heaviness of the limbs, which gradually increase to complete paralysis.

3. Vasomotor and secretory disturbances: Hysterical patients suffer frequently from paroxysms of palpitation. During these attacks the pulse is at first frequent, small and hard; the skin is pale and cold; there is a feeling of fullness and oppression in the chest. They are also liable to fainting fits, caused doubtless by sudden anemia of the brain. Hysterical patients suffer from various anomalies of secretion and exertion. Increased flow of saliva is not an unusual symptom after a hysterical attack, and it occurs occasionally independently of the fits. At other times an abnormal dryness of the mouth, along with great thirst, is present, inducing the patients to drink large quantities of fluid.

4. Psychical Disturbances: The chief mental characteristic of hysterical patients is an excessive emotional excitability, unchecked by voluntary effort, which finds expression in various ways. Laughter and sobbing not only alternate but coexist, and often without any sufficient reason for either. Another mental peculiarity of hysterical patients—a peculiarity which lies at the root of almost all their other mental derangements—is craving for sympathy. It is this desire for sympathy that prompts hysterical patients either to exaggerate a real ailment or to feign illness.

Treatment.—One of the most remarkable cults that has made its appearance in modern times is that to which the name "psychoanalysis" has been given by Freud. Its aim is the determination of the repressed mental processes responsible for the symptoms of the various psychoneuroses, and for other phenomena of the normal and abnormal mind. It will be remembered that, owing to the operation of the censure, these processes are prevented from appearing in consciousness except in a distorted and unrecognizable form, and that, therefore, the patient is himself unaware of their real nature. Hence, in order to achieve its end, psychoanalysis must in some way circumvent, as it were, the censure.

Freud originally employed hypnotism for this purpose (the so-called "cathartic" method), because in the hypnotic state the resistance of the censure is generally greatly lowered. Later, however, he found this procedure to be inadequate and subject to various disadvantages, and he has now altogether abandoned it in favor of his modern method of psychoanalysis. This comprises two more or less independent operations, (a) free associating and the (b) interpretation by the physician of the memories thereby attained.

(a) Free Associating.—The patient is encouraged to unburden his mind freely to the physician. He is asked to concentrate his mind upon a given symptom or circumstance and to relate every idea or memory which occurs to him, but to make no attempt to direct or control the flow of his thoughts. It is necessary that he should adopt an entirely non-critical attitude, recording everything which passes through his mind, however trifling, unpleasant, or irrelevant this may seem to be. The adoption of a non-critical attitude lowers the resistance of the censure, and it is found that the ideas then produced are all conditioned, to a greater or less degree, by the pathogenic complexes.

(b) Interpretation by the Physician.—Various peculiarities in the character and production of the images and memories described by the patient, in particular certain phenomena, indicating that resistance is being exerted by the censor, enable the physician to estimate their significance, and to determine ultimately the exact nature of the underlying complex as an example of the way in which the censure manifests itself during an analysis may be mentioned the stoppages observed in the train of ideas produced by free associating. The patient states that his mind is blank and that nothing occurs to him. After some persuasion on the part of the physician, however, an idea is finally produced, but the patient brushes it aside as trivial, irrelevant, or absurd. The real ground of the former suppression of the idea is, of course, that it is connected with the pathogenic complex—the belittling of its importance is an expression of the resistance offered by the censure. The method of interpretation has now been developed by Freud into a complicated technique requiring years of study and practice before it can be efficiently employed. The scope of the present review does not permit of any detailed description of its nature.

511 East Eleventh Street

DONOR AND RECEPTOR IN REGARD TO BLOOD GROUPS.

By A. L. BENEDICT, M.D.,

BUFFALO, N. Y.

The following simple rule will prevent error in transfusions. Consider that the numbers 1 to 4 of the blood groups represent successively higher levels. The flow of blood from donor to receptor should be made in the same way that water flows, from any higher to any lower level, or on the same level—never uphill. The sole exception is that transfusion between the second and third groups should never be made in either direction.

Attention may be directed to the macroscopic method of determining the blood group of an individual, simply by having on hand known sera of the second and third groups in ampoules, and adding a drop of the patient's blood to these two sera on a slide. Precipitation occurs in both if the blood is from a person of the first group; in neither if he is of the fourth; in the second alone if he is of the third; in the third alone if he is of the second.

The fourth group are universal donors, the first universal receptors. Conversely, the fourth group

are receptors from their own group only, the first donors only to their own group.

The relative frequency of individuals of the respective groups, in order, is stated to be 5, 40, 10, and 45 per cent., approximately. By the law of chance, assuming that any person chosen as a donor or any requiring transfusion is a member of a practically infinite number of individuals so that no subtraction is necessary in calculating the number of receptors for any given donor, or vice versa, the proportion of safe transfusions without precautions may be calculated as follows:

First group: 5 in 100 will occur as donors, 5 in 100 of the same group as safe receptors.

Second group: 40 in 100 will occur as donors, 40 in 100 of the same group and 5 in 100 of the first will occur as receptors.

Third group: 10 in 100 will occur as donors, 10 in 100 of the same group and 5 in 100 of the first will occur as receptors.

Fourth group: 45 in 100 will occur as donors, and all of the potential receptors may be safely transfused.

Hence it may be concluded that by virtue of the chance that the donor is in the first group: 25 in 10,000 transfusions will be safe.

Second group: 1,800 in 10,000 transfusions will be safe.

Third group: 150 in 10,000 transfusions will be safe.

Fourth group: 4,500 in 10,000 transfusions will be safe.

Total safe transfusions in 10,000, 6,475 (64.75 per cent. of total). It should be stated that the fact that a transfusion is not safe on account of incompatibility of blood groups, does not necessarily mean that it is fatal, or even attended by conspicuous reaction. It should also be considered that the calculations are made on approximate estimates of the distribution of blood groups, which may vary considerably in different races or nationalities, and that comparatively small differences in relative incidence, multiplied by the corresponding different numbers of potentially safe receptors, might change the total proportion of safe transfusions very markedly. Without going into details, however, and with apology for assuming conditions contrary to fact as generally accepted, it may be pointed out that a reversal of the relative proportions of the first and fourth and second and third groups, or a transfer of the high percentages to the first and fourth groups, would not make much difference in the average risk. On the other hand, if the high incidence occurred in the middle groups, the relative safety of promiscuous transfusion would be just about 50 per cent., and if the groups were evenly distributed it would be 56.25 per cent.

It is suggested that these statements be subjected to criticism, as there are many fallacies and opportunities for blunders in applying the law of chance; also that it would be of great value to have series of determinations of blood groups from widely different localities, especially with regard to race and nationality, and candid reports of actual mortality and conspicuous reaction in known series of promiscuous transfusion.

SYMPTOMS ASSOCIATED WITH DENTITION

By ELLSWORTH MOODY, M.D.

JOPLIN, MO.

CHIEF OF STAFF, JOPLIN CHILDREN'S HOSPITAL.

Curiously enough, there is almost absolute uniformity in American text books on Diseases of Children, concerning the question of the relation of dentition to certain disorders to which babies are liable. The American authors unite in discouraging the idea that dentition can be anything but a normal physiological process unaccompanied by symptoms other than the actual appearance of the teeth. They insist that a great deal of harm can be done by the assumption that teething can produce cough, diarrhea, or fever and suggest quite properly that the attempt should be made to educate all parents to the idea that these special symptoms may be of grave importance and should be attended to. However, they all state that the laity have observed for generations that certain symptoms are quite frequently associated with dentition, and Kerley states that there may be some trouble with weak children and cites the case of a rachitic babe who had convulsions associated with appearance of the first three teeth.

The British authors, equally uniformly, feel that teething is not infrequently associated with certain symptoms and Still devotes a good many pages to the symptoms which may arise and "protests against the tendency to assume that because dentition is a physiological process therefore it is incapable of causing disturbance of health."

Unquestionably it would be quite difficult to prove absolutely that certain symptoms are due to teething and to nothing else. However, the experience of trained observers and of the more intelligent parents must be given some weight, and certainly it is logical to suppose that nervous children may be upset in the same manner that nervous women are upset by the normal and physiological process of pregnancy. Why we should admit that "nervous coughs" and "nervous diarrhea" may exist in adults and deny the possibility of their existence in infants, and their being precipitated by such a process as teething does not seem logical.

I have recently seen several cases where symptoms, ascribable to other causes, have developed when a tooth was just beginning to push through, and have subsided coincident with the eruption of the tooth. Every method has been used to determine whether the symptoms were not the result of some other cause but we have been unable to discover any. The following illustrative cases are not offered as proof of the contention that they are the result of teething in any sense of the word, but it is felt that the coincidence is very striking. Nor would any attempt be made to discourage the purpose of American pediatrists to have children seen by a trained medical man as soon as these symptoms develop. While agreeing absolutely with the idea that a great deal of harm can be done by assuming that no treatment is necessary for these conditions, because unquestionably they should be taken care of intelligently regardless of the cause, I do also feel that we should pay rather more attention to dentition as a cause of mild disturbance.

Case I.—F. J. J. Male. Age 10 months. Brought to office because of cough. Physical examination absolutely negative except for swollen gums over the lateral incisors both above and below. There is a history of a cough preceding the eruption of the middle incisors which cleared up after they had come through. Blood count normal; urine negative; temperature 98.8° by rectum. No medication was suggested and after two days of careful physical examination and finding no other pathological reason for the cough; the gums over the upper lateral incisors were scraped with a scalpel allowing the teeth to come through. The cough disappeared immediately to recurr at the end of four days, when the lower gums were scraped through. The cough again stopped almost immediately.

Case II.—M. R. J. Female. Age 9 months. Seen because of convulsions. Temperature 103° by rectum; general physical examination negative; reflexes normal, blood, spinal fluid, and urine quite negative. There was, however, bulging of the gums of the upper central incisors which had not erupted. A second convulsion came on during the examination. No treatment other than lancing the gums was given at this time. Within four hours the temperature had dropped; the child was apparently normal and there were no more convulsions.

There have been under observation recently four cases whose history corresponds pretty closely to that of the first case cited. All cleared up within twenty-four hours after the eruption of the teeth. In one case, elixir of terpin hydrate with heroin was given to an eleven months old babe but did not affect the cough. Lancing the gums apparently cured her.

There cannot be any doubt that there is some relation between the symptoms these children haye presented and their teething although I will not pretend to explain the mechanism connecting the cause and the effect.

Frisco Building.

A CASE OF SCARLET FEVER WITH PNEUMONIA AS A COMPLICATION.

By A. LOBELL, M.D.,

NEW YORK.

The following case seems worthy of record for the reason that (1) according to the text books pneumonia is a rare complication of scarlet fever; (2) in this case several complications were present, yet the patient recovered; (3) the pneumonia itself was for a time difficult of diagnosis.

R. S., female, age 4, had had measles, pertussis, and several attacks of tonsillitis. Her present history dated back to April 14, when she began to complain of a sore throat, fever, and vomiting, and a rash appeared on the face the next day. Her temperature was 103°, pulse 126, respiration 26. There was an intense erythema of the face, a punctiform eruption of the entire body, with scattered areas of hemorrhagic spots. The angina was pronounced and there was an exudate on the tonsils which gave a negative diphtheria culture. Subsequently desquamation was very marked, so that there seems to remain no doubt as to the diagnosis of scarlatina.

On April 25 she developed a purulent otitis media of the left ear which continued to discharge for five weeks. There was congestion of the right ear, but the drum was incised early and the congestion subsided in a few days.

On April 28 she began to cough and complained of pain in the back part of the chest; temperature 104°, pulse 130, respiration 36. Two days later there was definite dullness over the right lower lobe extending upward to the seventh rib and laterally not quite to the axilla. Vocal fremitus was absent and the voice was not transmitted; the vesicular murmur was also absent except in one area about the size of a silver dollar between the eighth and ninth ribs, and more toward the median line there was distinct bronchial breathing; in fact, it was so marked that one might even call it cavernous breathing. Over this small area the percussion note was also dull.

The temperature ranged between 100° and 105° F. for about twelve days. The dullness increased in intensity almost to flatness. The heart was not displaced apparently. The cough was distressing and spasmodic at times. The expectoration was profuse, tenacious, and had no special odor. The child suffered intense pain at frequent intervals, there was also tenderness over the affected area. The temperature presented wide remissions and she was drenched in perspiration. She had a hectic flush and an anxious appearance.

The chest was aspirated on two occasions. Once we obtained 5 c.c. of pure blood and once it was a dry tap.

The *x*-ray report is as follows: Right lung shows a diminished illumination at the base more to the median line than in the axilla. No pulmonic markings are visible through the shadow. The costophrenic sinus is not obliterated, but the dome of the diaphragm is partially obscured by the shadow. The left lung is normal.

It was of vital importance to decide whether we were dealing with a case of lung abscess, a sacculated empyema, or an irregular pneumonia. From the *x*-ray we were unable to distinguish in this case.

We decided to wait a few days so as to give the patient the benefit of the doubt before we attempted surgical interference. Fortunately her temperature came down by lysis during the next three days and she made an uneventful recovery in spite of an acute nephritis which she developed subsequently.

The physical signs of the chest during convalescence were a gradual diminution of the dullness and a concomitant appearance of the vesicular murmur but we did not hear any râles of resolution.

We believe we were dealing with a pneumonia in which a mucous plug obstructed a main bronchial branch and caused the anomalous physical signs. We regret that we had no facilities for blood counts and cultures of the sputum and blood.

320 East 166th Street.

Medicolegal Notes.

Liability of Municipal Hospital.—The rule is well settled that a municipal corporation is not liable for the negligent acts of its employees in the performance of public or governmental duties. The Kentucky Court of Appeals holds that in the management of its hospital, maintained under the power given it by Ky. St. §3290 to establish hospitals and make regulations for their government a city is performing a governmental function and is not liable for injury to a patient caused by a nurse's negligence. The fact that some of the patients were pay patients was immaterial.—Browder v. Henderson (Ky.), 207 S. W. 479.

Purpose of Requiring License to Practise.—In an action for medical services in the Illinois courts it appeared that the plantiff was not licensed to practise in Illinois and that while the treatment was administered by him in Missouri, he diagnosed the case in Illinois. In reversing a judgment for the defendant the Illinois Appellate Court held that the purpose of the Illinois statute requiring a license to practise medicine is to prevent persons who are not qualified from practising medicine upon the citizens of the State, and it applies to one who examines a person, diagnoses his ailment and professes his ability to treat, even though the actual treatment is administered in another State. —Bailey v. Niebrugge, 211 Ill. App. 82.

Hospital Records as Evidence.—The New York Appellate Division holds, in a personal injury action, that records of a hospital in which the plaintiff was treated were not admissible in evidence without proof of their correctness and the opportunity to examine as witnesses the persons by whom they were made, even though the attending physicians were absent from the jurisdiction.—Dougherty v. Kalbach, 175 N.Y. Supp. 837.

MEDICAL RECORD.

THE DIAGNOSIS OF JEJUNOCOLIC AND GASTROCOLIC FISTULÆ.

ERUCTATIONS with a fecaloid odor, vomiting with the same odor and the syndrome of incomplete intestinal occlusion, are the symptoms which, in a subject who has undergone a gastroenterostomy, should lead to the diagnosis of a jejunocolic or gastrocolic fistula following a perforating ulcer. Thus set forth, the problem appears quite easy to solve, but all these signs have not the same diagnostic value and some of them may give rise to erroneous interpretations.

The fecal smelling eructations are never wanting and therefore are of great importance; they occur in both jejunocolic and gastrocolic fistula. Vomiting, although less constant, is of equal diagnostic value when it is present. In both types of fistula the vomitus or the gastric contents removed by the sound, have a fecaloid odor, but when the vomitus contains matter having a fecal aspect and an examination confirms its fecaloid nature, it is notable that there is either jejunocolic fistula situated in the immediate neighborhood of the gastrointestinal opening or, and more particularly, a direct communication between the stomach and large intestine.

The existence of a gastrocolic fistula may also be demonstrated by Kaufmann's test with grains of lycopodium stained with gentian violet and also by radioscopic examination. Kaufmann's test must not be too greatly relied on because it has been negative in some positive cases, but it is only right to add that in at least one of these cases the fistula when examined at operation appeared to be very narrow and as if undergoing closure. On the other hand, in this same case radioscopic examination confirmed the existence of the fistula by showing the passage of the bismuth from the stomach into the gut through two quite distinct openings, and the almost instantaneous arrival by the bismuth in the descending colon and sigmoid flexure.

Diarrhea occurs after gastroenterostomy although no fistula has developed. It occurs either within a few days after the operation or at a rather late date. In the former case it is due to irritation produced by the chyme on an intestine unaccustomed to its contact; in the latter it is the result of an insufficiency of the biliary and pancreatic secretion. It might also be reasonably supposed that the diarrhea can be due to a disturbance of gastric chemism and evacuation and this undoubtedly is sometimes the case; but however this may be, medical treatment will cause it to subside quite rapidly. It is also more than likely that some cases of serious diarrhea following gastroenterostomy were, in reality, due to a jejunocolic or gastrocolic fistula which was not recognized.

Intestinal splashing might, on superficial examination, be mistaken for gastric clapotage. The persistency of the phenomenon after removal of the gastric contents with the sound, the absence of concordance between the two extreme points where it can be elicited, and the limits of the insufflated organ will avert the possibility of a dignostic error. It is well to recall the analogies which exist between clapotage and the two important symptoms of hourglass stomach, namely ectasia ventriculi paradoxa of Jaworski, and Bouveret's sign. The first is characterized by the persistence of clapotage after emptying the stomach with the sound, while the second, which belongs to cases of gastric biloculation where, on account of a special arrangement of the area of stenosis insufflation does not inflate the upper pouch, consists of an absence of concordance between the fixed limits of the stomach by clapotage and those that it appears to reach when insufflated.

The resemblance between these various symptoms is such that the diagnosis may well remain in doubt, but sometimes the question may be settled by the *x*-ray although this, too, may fail. Nevertheless, the fact that fecaloid eructations occur after a gastroenterostomy should have the greatest weight in the diagnosis. When the syndrome of incomplete intestinal occlusion is present, it is still these last two elements of diagnosis which should absolutely indicate the cause of the occlusion.

THE QUESTION OF CHOLECYSTECTOMY.

IT is no longer the time when surgeons hesitated to remove the gall bladder on the pretext that this organ possessed a distinct physiological function. The number of cholecystectomies has singularly increased with improved technique, likewise there has been a great decrease in the mortality percentage. There are unquestionably some able men like Kocher, Mayo Robson, and others who are opposed to removal of the gall bladder, but nevertheless it seems only logical to remove a seriously pathologically changed organ and also when it contains calculi which are only waiting for a chance to go further in the biliary tract and there set up other complications. Cholecystectomy would seem to be an ideal operation if, besides the mechanical phenomena caused by the presence of the stones, it were not necessary to take infection of the gallbladder and biliary tract into consideration. In order to deal with this infection, drainage of the gallbladder has appeared to be an excellent means. If there is infection of the main portion of the bile

passages they must be put at rest, but it is none the less true that when the gall bladder is alone clinically and microscopically at fault, cholecystectomy is enough to cure the patient.

The indications for operation are now more precise and the too absolute rules of former days no longer apply to cholecystitis, and while nearly everybody admits the value of choledochotomy and hepatic drainage in the treatment of a calculus lodged in the choledochus and infection of the principal bile ducts, the same cannot be said as to the value of simple cholecystectomy in the treatment of biliary lithiasis. The partisans of this operation defend it with the same ardor as those who maintain that cholecystectomy alone is insufficient to obtain a cure of calculous cholecystitis and that drainage of the biliary tract should invariably be resorted to. But the number of permanent cures effected by removal of the gallbladder is now convincing and it would seem that the indications for this operation can at present be stated with a considerable degree of certainty.

While both physicians and surgeons agree that simple hepatic colic and angiocholitis are exclusively in the domain of medicine and that a calculus lodged in a biliary duct is exclusively surgical, as no accord has been reached in respect to the treatment of calculous cholecystitis, but it seems safe teaching to say that the medical treatment of biliary lithiasis is insufficient in the case of calculous cholecystitis and that the best treatment for this lesion is cholecystectomy. This operation removes a physiologically insufficient viscus the ablation of which produces no disturbance in the organism.

Removal of the gall bladder should be preferred to cholecystotomy in the treatment of chronic cholecystitis and should be undertaken at a later date when drainage of the gallbladder has been done on account of an acute cholecystitis. Cholecystectomy is an excellent operation in hydropsy of the gall bladder and in the majority of cases of cholecystitis accompanied by marked digestive disturbances. It may also bring about a cessation of the pancreatic distubances in cases of cholecystopancreatitis. The operation should be completed by drainage of the principal ducts in cases of lithiasis or infection of the hepatic ducts or the choledochus.

RADIUM TREATMENT OF CANCER.

THE effects of and efficacy of radium have been very widely discussed of recent years. As a therapeutic agent it has been extolled to the skies and condemned without reservation. Soon after its first introduction it suffered severely from the exaggerated and indiscreet praise of its too enthusiastic advocates. In the reaction which followed it was freely stigmatized as absolutely useless and even harmful. The medical profession is now coming to a fair estimate of its worth, avoiding excessive praise on the one hand and equally foolish condemnation on the other. The conclusion has been arrived at that radium is neither a "cure all" nor a useless or harmful means of combating certain diseases, but when employed properly, that is in correct dosage and with exact knowledge as to its application, is a most valuable remedy.

W. H. B. Aikins of Toronto read a paper on radium at the meeting of the American Radium Society, Atlantic City, June 9, 1919, which is published in the *Medical Press* for October 8, 1919. In this paper it is explained how necessary it is to recognize the limitations of radium and not to expect too much from its employment. Aikens reviews the history of radium in the treatment of cancer and states it holds a firm, almost unassailable position as regards the treatment of cancer of the face. It may be relied upon in a large proportion of these cases to bring about a permanent cure without leaving the disfiguring and contracted scars which so often result from surgery, and which so frequently are the site of recurrence of the trouble. In such cases there is no other treatment which can compare with radium in the excellence of its cosmetic results. Further, Aikins says, radium may be recommended in this connection because of the ease and painlessness with which it can be applied. Not only in malignant but also in benign diseases of the skin radium has proved its value.

Surgeons for the most part regard radium as chiefly useful as an adjunct rather than a substitute for the knife. As to this, while Aikens does not admit that its main value rests in its postoperative efficacy, he does regard it as peculiarly useful in this field. He quotes from the Report of the London Radium Institute, issued at the end of 1918, in which it is stated that between 1911 and 1914 a large number of cases of cancer were operated upon by surgeons of high standing, and the operations were so extensive that in the opinion of the operators recurrence was inevitable. After postoperative treatment with radium, recurrence took place in less than 20 per cent. of the cases, a result which is believed to be unequaled even in the records of selected cases operated upon by surgeons of extensive experience. One of the most beneficial effects of radium is the manner in which it will often, perhaps generally, relieve the distressing features of incurable cases and thus modify the unpleasant symptoms characteristic of the final stages of the disease, and render the last days of the patient at least endurable. This precious action of radium has been notably demonstrated in advanced cases of cancer of the uterus. Aikins does not in any way overstate the case when he says that the present position of radium therapy is very encouraging and that radium has amply justified its use by its palliative properties in these hopeless cases.

MIGRATIONS OF THE ASCARIS LUMBRICOIDES.

INFECTIONS with the *Ascaris lumbricoides* have long been familiar to medical men and their tendency to turn up in unusual locations has filled

many pages in medical literature and caused much disturbance to the patient and his family. The fact that early in its development, this parasite is regularly an inhabitant in the lungs, is not generally known, although Stewart began writing on the subject in 1916. Ransom calls attention to these facts in an article (*Jour. Am. Med. Assn.*, 1919, lxxiii, 1210) which includes also a report on some of his own investigations into this subject. The procedure is as follows: the eggs of the round worm, if swallowed, hatch in the small intestine and the newly hatched larvae leave the intestine and migrate to the liver or possibly directly to the heart. They then progress through the circulation into the lungs where they are arrested by the capillaries. They enter the air vesicles and pass by way of the bronchioles, bronchi, trachea and esophagus, into the small intestine where, if the animal is a suitable host, they settle down and develope to maturity. Their subsequent wanderings are apparently without fixed purpose or definite program. These observations have obtained experimental verification. Their significance lies in the fact that during their stay in the lungs, the embryos may cause serious damage to that organ, producing multiple small hemorrhages, bronchitis or even pneumonia. How serious a factor this is in the pulmonary conditions of children it is difficult to determine but it is probably not inconsiderable. Certainly the round worm is not an infrequent finding. It would be of interest to obtain careful histories of pulmonary conditions in all of those harboring the worm and to collect this information in one place.

Septic Infarct Causing Rupture of the Spleen.

An unusual case of septic infarct causing rupture of the spleen, hemorrhage, and death has recently been reported by Alan H. Todd (*British Journal of Surgery*, July, 1919, vi, 23). The patient received severe shell wounds of the left arm, shoulder, and thigh and a compound fracture of the right leg on Dec. 19, 1917. In this latter injury both the anterior and posterior tibial arteries were torn and there was gas bacillus infection of the tissues of the leg. A circular amputation just above the condyles was done at the Casualty Clearing Station and 500 c.c. of blood transfused. The other wounds received appropriate treatment at the same time. On the following day the patient received another transfusion of 500 c.c. of blood. On December 28, nine days after the receipt of his injury, the patient was admitted to Lewisham Military Hospital, his amputation wound at that time exuding much thick green pus and the granulations were exuberant and foul. Two days later he was given 500 c.c. of antitetanic serum. On January 3 he had an irritating cough with some expectoration; his temperature chart showed a moderate irregular pyrexia. On January 9 he complained at night of a sudden stabbing pain over the left lower ribs, and five hours later he suddenly collapsed and died before medical aid could be obtained. Autopsy showed rupture of the spleen and a very large amount of free and clotted blood in the peritoneal cavity. The spleen pulp, as much of it as was recognizable, was very soft and there was a thick coating of fibrin on the surface of the organ. Blood culture was negative and no proof of general septicaemia could be adduced. Todd calls attention to the fact that cases of infarction of the spleen are common enough; but that it is very rare that the spleen, unless a malarial one, ruptures spontaneously and causes death from sudden severe hemorrhage.

Biological Tests for Pregnancy.

At the recent session of the French-speaking Association for Gynecology and Obstetrics, reported in *La Presse Médicale* (October 8, 1919, xlvii, 41), Bar and Ecalle first mention the complement deviation or specific test which they regard as impracticable. To obtain it the placenta must be at least 4 months old and the serum of the mother in the fifth month, and at best the reaction is inconstant. Abderhalden's reaction is positive for the gravida in 100 per cent. of cases but is also positive in 33 per cent. of nongravidæ. It is positive in ectopic pregnancy so long as the fetus lives. It is positive early in gestation, first appearing in the second month. The antitryptic reaction is not dependable, while the cobra venom test has also but a relative and limited value. To sum up, the clinical advantage does not begin to outweigh the great outlay of time and trouble. In the discussion Fieux and Mauriac mentioned their experience with the complement deviation reaction, which was of much interest, but would not come up to the requirements of forensic medicine. Hauch of Copenhagen spoke of Favarius's test introduced in 1918, which is in reality only indirect like some others; that is, it is really a test for the coagulation time of the blood. Negative tests are of no value. Of others who discussed the subject none was very optimistic.

News of the Week.

Bubonic Plague in New Orleans.—Four cases of bubonic plague, two of which resulted in death, were reported during the last week in October in New Orleans, according to announcement by Dr. Oscar Dowling, President of the Louisiana Board of Health.

Vocational Rehabilitation for Those Disabled in Industry.—The Smith-Bankhead bill, which has just passed both Houses of Congress, provides vocational rehabilitation, similar to that now in operation for disabled soldiers and sailors, for persons disabled in industry or otherwise. The bill provides an appropriation of one million dollars yearly to enlarge the scope of the original Smith-Hughes Act, creating the Federal Board for Vocational Education and its recent extension to cover war cripples so as to assure the maimed victims of industrial accidents also the opportunity for vocational retraining into skilled occupations. "There are at present," it was pointed out in the Congressional debate, "more than one hundred thousand permanently incapacitated workers in the United States, who will be benefited by this legislation, and this large army of casualties of peace is being increased at the rate of 11,500 every year." Under the bill as passed by Congress the individual States must provide at least one dollar

for each dollar expended by the Federal Government on behalf of their own crippled workers. Several States have recently taken favorable action in anticipation of Congressional cooperation now assured in the Smith-Bankhead bill.

Health Insurance Opposed.—The Associated Physicians of Long Island, at their sixty-fourth regular meeting held at Garden City, L. I., October 25, 1919, devoted the entire session to a discussion of Compulsory Health Insurance. Addresses were made on this subject by Dr. John J. O'Reilly and Dr. Harris A. Houghton, after which resolutions were passed placing the society on record as opposed to all forms of compulsory health insurance.

Women Doctors in England.—According to a statement published in the *British Medical Journal*, May, 1918, there are 2,250 women doctors in England, which is several times more than for the corresponding date of 1914. One out of every five doctors who completed their training in England this year was a woman.

Society to Aid Blind Incorporated.—The Permanent Blind Relief War Fund for Soldiers and Sailors of the Allies has received incorporation papers in New York State. The object of the corporation is the relief of soldiers and sailors of the United States and of the nations associated with it in the war who have been blinded in the war or as a result thereof. Sir Arthur Pearson is one of the patrons of the new organization.

An American Field Hospital Finally Stationed.—An American Field Hospital which traveled from Hoboken to France, from Bordeaux to Germany, from Trier to Constantinople, and from Constantinople to Ekaterinburg, Russia, has finally been placed with the southern division of General Kolchak's army. The hospital was shipped to France for the use of the American Expeditionary Force, but the signing of the armistice made it superfluous property. There is no more critical need for medical service than in southern Russia. The Red Cross has, therefore, delivered the modern mobile plant, valued at $100,000, for the use of the Cossack forces. The hospital has five hundred beds and two operating rooms and includes all equipment needed for immediate operation.

An American Hospital in Paris.—An American hospital is to be opened in Paris by the Red Cross especially for the treatment of soldiers disfigured by face wounds received in action during the world war. The establishment of the hospital was made possible by the donation to the American Red Cross of a fund totaling $32,742.95. The gift was made by the American National Committee for the Foundation of a Special American Hospital in Paris for Wounds of the Face and Jaw. The cooperation of one of the foremost French face and jaw surgeons has already been obtained.

New York Working Women Physically Unfit.—Dr. Kristine Mann, of New York, in an address before the International Conference of Women Doctors, recently held in this city, cited statistics showing that 92 per cent. of the working women of New York are below par physically and that 506 out of every 1000 lose time from their work on account of sickness. She attributes this state of affairs to the need of instruction in the hygiene of daily life, and to lack of time in which to take exercise. She makes a plea for instruction in the fundamentals of sex hygiene, the establishment of health and recreational centers, and the provision of bath houses and swimming pools for women.

Health Department Guards Against Importation of Rats.—As a result of the discovery by Health Commissioner Copeland that "rat guards" are not always properly attached to cables which tie up freight vessels in the Port of New York, orders have been issued by the Health Department to the owners of incoming vessels to see that "rat guards" are attached to vessels and to have incoming cargo ships fumigated at Quarantine.

New York Hospitals Meet Standards.—According to the report of the Hospital Standardization Committee of the American College of Surgeons, 199 hospitals of more than 100 beds in the United States and seven in Canada have measured up to the requirements of the college. Twenty-six of the ninety hospitals in New York State have been approved by the surgeons. New York State has the highest average of hospitals measuring up to the standard of any State in the Union.

Dr. Charles M. Williams, of New York, has returned from service in the American Expeditionary Forces and resumed the practice of medicine at 48 East Forty-ninth Street.

Dr. J. Breckinridge Bayne, of Washington, D. C., who saved southern Rumania from the scourge of typhus during the German occupation of 1917-1918, and who received the highest decoration from King Ferdinand, has again been honored by the Rumanian Government. The King and Queen have personally thanked him for his services and presented him with the Order of Regina Maria, First Class.

Acquitted of Opium Charge.—Dr. Lewis Falk and Julius Nelson, a druggist, were recently acquitted in the Federal District Court of New York of charges of violating the Harrison drug law by furnishing opium and other drugs to addicts.

Obituary Notes.—Dr. CUSHMAN A. SEARS died from heart disease at his home in Portland, Me., on October 21, aged 79 years. He was a graduate of New York University Medical College in 1862, and was for many years medical examiner of Portland.

Dr. GEORGE L. WAKEFIELD, a graduate of the Hahnemann Medical College, Chicago, in 1882, died at his home in Manchester, N. H., on October 4, aged 72 years. He was a civil war veteran and was wounded four times.

Dr. CHARLES E. NEWCOMB, a graduate of the University of Vermont College of Medicine, in 1880, died at his home in Grantham, N. H., on October 1, aged 61 years. Dr. Newcomb formerly practised in Haverhill and Montpelier.

Dr. JOSEPH MOSHER of Tuxedo, a graduate of New York University Medical College, died at White Plains, Pa., on October 11, aged 33 years.

Dr. JAMES FREDERICK SMITH died of pneumonia at his home in New York on October 18, aged 62 years. He was a graduate of the College of Physicians and Surgeons in 1882, and for a time practised at Westford, Mass., and Bangor, Me. Later he removed to New York, where he was assistant surgeon at the Manhattan Eye, Ear, Nose, and Throat Hospital and in the Nose and Throat Department

of the Post-Graduate Hospital. He was a member of the Medical Societies of the County and State of New York, of the American Medical Association, and of the New York Academy of Medicine.

Dr. WILLETT WELLES BROWN of Montclair, N. J., a graduate of the New York Homeopathic Medical College in 1910, died of pneumonia at his home, on October 18, aged 36 years.

Dr. HORACE PERKINS MAKECHNIE, a graduate of Bellevue Hospital Medical College, in 1879, and an ex-president of the Somerville Medical Society, died suddenly of heart disease at his home in Somerville, Mass., on October 17, aged 78 years.

Dr. ELBRIDGE S. PIXLEY, a graduate of the Eclectic Medical College, Philadelphia, in 1878, died at his home in Great Barrington, Mass., on October 11, aged 87 years.

Dr. HENRY W. STEPHENS, a graduate of St. Joseph's Medical College, Missouri, in 1883, died after a long illness at his home in Anaconda, Mont., on October 12, aged 58 years. He was alderman of Anaconda in 1898 and mayor in 1900.

Dr. CUSHMAN A. SEARS, a graduate of Bellevue Hospital Medical College, in 1862, died at his home in Portland, Conn., on October 20, aged 82 years.

Dr. GEORGE VINCENT HUDSON, a graduate of New York University Medical College, in 1867, died at his home in Brooklyn on October 24, aged 76 years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, October 10, 1919.

Medical Exhibition in London.—The London Medical Exhibition which had not been held since 1913, the year of the International Medical Congress in London, resumed its sessions on October 6-10. The meeting took place in the Central Hall, Westminster, and was interesting from many points of view and unique in one. At all other exhibitions of a similar character held in Great Britain before the war it was plainly evident that the German manufacturers of drugs, chemicals and surgical instruments had almost control of the British market. In fact, the fear was freely expressed by the timid that, lacking German assistance, the supply of drugs, chemicals and so on would be totally inadequate to the demand. It was predicted by the pessimists that neither in quality nor quantity could the Britisher hope to equal the German manufacturers and that indeed most of the synthetic drugs could not be made in England. For some time it had been known that these prophets of evil were wrong but it remained for the Medical Exhibition to provide public practical proof of these erroneous surmises. The most striking feature of the exhibition was the exemplification that no longer is there any need to lean upon German science or manufacture for drugs or chemicals, for in this respect Great Britain is now self-supporting. Another lesson which has been learned from the inability to obtain from Germany those synthetic preparations with which the civilized and even uncivilized world used to be flooded, is that the world can very well do without many of them, and that some of the older vegetable drugs, in the long run, answer the purpose a great deal better. A survey of the exhibits showed very clearly the direction in which postwar medicine is developing most rapidly. The advances of vaccine therapy were well shown, and also those in organotherapy.

Pay Wards in British Hospitals.—The British medical profession and public have always congratulated themselves on their free hospital system and, perhaps, have been inclined somewhat to depreciate the system more or less prevalent in America of "paying hospitals." However, it seems now that both the profession and public are changing their views and are beginning to recognize the merits of the American methods and are even thinking of adopting or partly adopting them. It is patent that something must be done in the near future to introduce on an extended scale a system by which the middle classes who cannot afford the high cost of treatment in a private nursing home and yet are not sufficiently poor to be admitted to a public hospital, may obtain efficient treatment at a moderate cost. In most of the London and in, perhaps, the majority of the hospitals in all parts of Great Britain in the charters of incorporation the duties of the hospitals are defined as applying only to the "poor" sick and disabled persons who should appear real objects of charity. In the first instance, therefore, it is obvious that a large number of British hospitals must alter the wording of their charters before they can be entitled to institute a pay ward. Moreover, it is by no means easy to decide who are objects of charity, especially as the status of patients has changed so greatly during the past few years. Ordinary laborers, painters, bricklayers, artisans, are now making $20, $25, and even $40 a week, whereas the clerk makes little more than $15. In bygone days the laborer who supported a family on $6 a week was as obviously a subject for charity as the clerk is to-day. The type of man for whom absolutely no arrangement of any kind is made is the professional man, or business man whose income is between $2,500 and $5,000 a year. He certainly would not be admitted as a charity case, and yet he cannot afford the heavy fees of an operation conducted privately in a nursing home. It is for this type of individual that the pay wards are most desirable, and for whom something will have to be done.

Views on Tuberculosis.—A series of lectures dealing with various phases of tuberculosis are to be held during the autumn and winter at the building of the Royal Institute of Public Health in Russel Square, London. These lectures are to be given by acknowledged authorities on the subject. The first was delivered on October 9 by Dr. Halliday G. Sutherland, who discussed the diagnosis of tuberculosis. It was pointed out that during the past five years the death rate from tuberculosis in England has risen by 12 per cent. Sutherland does not attribute this increase of mortality to the immediate effects of the war, that is, to the strain and tension of those dark years, nor even to the hardships which had to be endured, although, of course, these exerted their unfavorable influence, but he ascribes the high death rate mainly to the lack of butter in the diet, especially among children. During the war the absence of butter as an

article of food could be explained on sound grounds. But now, after the armistice has been signed for a year, it is difficult to understand why the British consumer is allowed only a paltry ounce or so each week of this most essential food. The lecturer also holds the lowered dietary of the war period and especially the lack of animal fats largely responsible for the ravages of and heavy death rate from influenza. In this connection it is interesting to learn that some of those who have made a close study of rickets, notably Dr. Eric Pritchard, are of the opinion that the withholding of butter from the dietary of young children and the substitution of vegetable margarine is a considerable factor in the causation of rachitic disease. Sutherland in his lecture quoted the well-known saying of one of the fathers of medicine that tuberculosis in its early stages is "easy to cure but difficult to detect," whereas in its later course it is "easy to detect but difficult to cure," and then discussed the problem of early diagnosis.

In making a diagnosis an accurate history of the case is very important. A patient is notoriously unreliable in his statements as to when the first symptoms appeared. Unconsciously he is apt to err in this respect and the medical man must cross-examine closely and carefully to arrive at the truth or even near to the truth. An instructive point brought out by the lecturer was that psychical symptoms are among the first to be noticed. The brain is early affected and definite symptoms of lowered will control exhibit themselves in various ways. The worship of Bacchus and Venus, which is frequently followed with such unrestrained ardor by tuberculous subjects, is due to this decline of will power. Tuberculous persons are prone to bursts of energy, followed by reaction and exhaustion. It is well known that many great men, of wonderful imaginative genius and whose output of immortal work has been very large, have been tuberculous. Witness Keats, Schiller and Stevenson, to mention only a few. The neurasthenic differs from the tuberculous person in that the former is always in an exhausted condition, while on occasions the latter is superabundantly energetic. Sutherland said that loss of weight is not an early sign of tuberculosis but a later. However, failure to gain weight in a child is a characteristic sign. One of the earliest signs in females is disturbance of the menstrual function. After a walk, in a tuberculous as in a normal individual, the temperature goes up, but the temperature of the tuberculous person does not go down after an hour's rest as it does in the normal individual. In many, probably in the majority of instances, surgical measures for the care of tuberculous glands are of little avail, because it is impossible to dissect out all these diseased glands. Sutherland holds that such glands can frequently be cured by tuberculin. After the age of twelve the Von Pirquet test is unreliable. Before that age it is of very considerable value. The tuberculin test is, on the whole, the most useful, but requires the possession of expert knowledge to interpret it properly. The *x*-ray screen is extremely useful in the diagnosis of tuberculosis in children. Finally, Sutherland lay stress on the paramount importance of early diagnosis of tuberculosis and declared that the art of medicine remains the art of diagnosis.

British Birth Rate Commission.—The British National Birth Rate Commission held its first autumn meeting recently. In a former letter mention has been made of the greatly increased infantile mortality and of the decreased birth rate in this country during recent years. The object of the Birth Rate Commission is to investigate into the causes of this calamitous state of affairs and to endeavor to suggest remedies. At the meeting of the committee Sir Rider Haggard gave evidence and his statements were so much to the point that no apology will be made for quoting some of them. He said in part that the birth rate had dipped below the death rate. Indeed, in the last quarter of 1918, when there was much sickness, he believed that nearly 80,000 more people died than were born in England and Wales. He admitted that Great Britain would be a much more comfortable place to live in with a population of, say, about 4,000,000, such as it possessed in 1570, than with a population of 40,000,000, which it possessed in 1911, for then those living would have plenty of room and money and could feed themselves on home-grown produce. But in the event of a war similar to that we had just experienced what would happen? Surely all we have would be taken and we must become slaves. With regard to remedies for decreasing population, the speaker pointed out that if it choose to do so the State could stamp out certain diseases that, directly or indirectly, tended to blast and sterilize the race; could subsidize motherhood, and, as a desperate ultimate resort, could undertake the care and upbringing of all children.

Scarcity of Midwives.—The Ministry of Health in a circular issued to supervising authorities under the Midwives Act and to local authorities responsible for maternity and child welfare schemes, draws attention to the regulations made by the Board of Education for the training of midwives and to the provision of grants for the purpose. Such grants will be paid to recognized institutions only in respect of approved courses at those institutions, and will be at a rate not exceeding £20 for each student who has declared her bona-fide intention to practise as a midwife or has been for not less than three years in full time employment as a health visitor, or has completed successfully a course of training approved under the regulations for the training of health visitors. The Ministry of Health published information as to other means for the training of midwives to which will be devoted sufficient sums of money and conclude the circular by pointing out that the comprehensive and systematic provision of midwifery services is still gravely inadequate in nearly all areas. The remuneration usually obtainable by practising midwives is insufficient, regarded as a reliable annual income, and is not commensurate with the responsible nature of the duties and the technical qualifications and skill required, nor does it attract and maintain an adequate supply of thoroughly competent women to meet the real needs of the community.

Opening of the London Medical Schools.—Owing to the strike of railway men, the London medical schools, a number of which had made arrangements for addresses and prize distribution at the opening of the winter session, had to postpone the opening ceremonies. However, some of these were held as

usual on Oct. 1. Dr. Addison, the Minister of Health, gave the introductory address at the Royal Free Hospital, London School of Medicine for Women. Sir John Goodwin distributed the prizes at St. Mary's Hospital, and Dr. S. Squire Sprigge, the editor of the *Lancet*, gave an address at St. George's Hospital. The distribution of prizes at Charing Cross Hospital which should have been performed by Sir Auckland Geddes on Oct. 1 has been postponed indefinitely. The opening of the session at University College was deferred until Oct. 6. Lectures began at St. Bartholomew's Hospital on Oct. 2. The opening ceremony at the Middlesex Hospital was postponed but the medical school reopened on Oct. 1. At St. Thomas's and Guy's Hospitals the work of the winter session began on Oct. 1. At the London Hospital the session reopened formally on Oct. 1. All the old students' dinners were postponed on account of the strike.

Obituary.—The death has taken place at the age of 72 of Surgeon General David Sinclair, C. S. I., formerly house surgeon to the Viceroy of India. Having taken his medical degrees at Aberdeen, he entered the Indian Medical Service in 1869. He held many important posts in the East, and for his services in Burma, where he was Superintendent General of Vaccination and chairman of the Civil Medical Department, he was given the C. S. I. in 1869. He was subsequently Surgeon General with the Government of Madras, and retired in 1904.

4. A Home for Aged and Infirm Physicians; an Outline of the Plan. Wolff Freudenthal.
5. Rupture of Membranes Fifty Days Before Labor. H. R. Coston.

2. Health Classes for Children and Their Effect on the Welfare of the Home and the Community. Ira S. Wile, after discussing the reasons for such instruction and the various agencies throughout the country which may be said to be engaged in one form or another of public education in matters concerning health, outlines the plan which he and his assistants employ in health classes connected with the dispensary of Mount Sinai Hospital of New York. At the time of admission, a card is given to the parent or guardian bringing the child. These cards are of three types, blue, yellow, and white, the idea of the three colors being to induce a certain measure of competition among parents and to stimulate each household to do its best. Each card has a quotation in English, rather suggestive of the phase of development of the possessor. It is assumed that these English quotations will stimulate sufficient interest among the foreign element to insure getting them translated by school children, social workers, or friends. These cards, with their appropriate quotations, are given out in sequence in accordance with the progress and interest shown by the holders thereof. After admission to the class, the next important matter is the waiting room. It should be a light, cheerful room, with ample ventilation, and provision for the comfort of adults and children. Discipline should not be formal; there should be an opportunity for relaxation and diversion. The wall is hung with informative posters and descriptive charts. A shelf is arranged upon which exhibits may be placed to illustrate foods, food values, and the relative economic and nutritive worth of articles of diet; proper types of wearing apparel; methods of making a home refrigerator, a fireless cooker, and similar items concerning which there is inadequate knowledge in the home. A bulletin board is of value in calling attention to matters of current interest relating to health. For children there are toys, games, books, rocking horses, blackboards, and other means of self entertainment or mutual amusement. The purpose is to take the waiting room out of the category of places that are morbid, to allay anxieties, dispel the possibility of fear, and create an atmosphere of friendliness, interest, and kindliness. From the waiting room the children go into small rooms or cubicles to be undressed, following which they are weighed and measured. The child is then stripped for examination by the doctor, who examines it carefully, paying particular attention to all organs of the body. In addition there is inspection of the spine and the extremities, the skin, etc. The physical examination should be comprehensive and, when necessary, should be repeated. Ocular, orthopedic, or other defects demanding special treatment are referred to the necessary department. The records are made while the child is dressing itself. After the examination, full directions are given to the parents or the child. The advice is supplemented with the information that the social visitor will call and explain further. A note is made upon the record blank as to the character of information which should be given at the home. The work of the class is supplemented by the home visitation of the social worker, who carries out the instructions that have been given, gives the advice which occasion demands, makes arrangements for conferences with other departments, and provision for appointments for whatever form of corrective work is necessary. The observations of the social worker are recorded upon the record blank. The writer summarizes health classes for children as the expression of humanized medicine, seeking through medical, psychological, educational, social, and economic means to build up generations of children who will be a credit to themselves, their families, and their countries.

2. The Pharmacology of the Local Anesthetics.—Cary Eggleston and Robert Hatcher state that acute intoxication in man from the use of local anesthetics is far more common than is indicated by the number of recorded cases. They therefore undertook to investigate the causes of such intoxication, the means of avoiding it and of combating it when it arose. This investigation included a study of the literature of the more important cases of human intoxication, and the performance of more than 300 experiments on cats. Nine local anesthetics were studied and the maximum toxicity of each was determined by rapid intravenous injection into cats. When large fractions of the minimal fatal doses are injected intravenously at intervals of from fifteen to twenty minutes, or when relatively dilute solutions of the drugs are injected slowly and nearly continuously, the several drugs can be divided into two groups based on the difference in their rates of elimination. Group 1 includes alypin, apothesin, beta-eucain, nirvanin, procain (novocain), stovain, and tropacocain, all of which are rapidl eliminated, so that several times the minimal fatal dose of any of these can be injected in the ways just mentioned in periods of one or two hours without causing death of the ani-

mal. Group 2 includes cocain and holocain, which are much less rapidly eliminated, and which therefore cause death in much smaller total doses when given as described.

When injected subcutaneously into cats the local anesthetics can again be divided into the same two groups, depending on their rates of elimination. The elimination of all the local anesthetics is accomplished almost entirely by their destruction in the liver. Various efforts were made to influence the toxicity of local anesthetics, including the administration of atropin or caffein prior to the intravenous injection of the anesthetics; the addition of sodium bicarbonate to the solution of the anesthetic just before intravenous injection, to liberate the base; the production of nervous exhaustion in the cat; severe acute hemorrhage by removal of one-fourth of the cat's total blood; and the production of narcosis by the administration of hydrated chloral. None of these had any effect. The employment of artificial respiration in combination with stimulation of the heart by the immediate intravenous injection of epinephrin was effective in resuscitating the majority of the cats after the rapid intravenous injection of doses of the local anesthetics up to twice the average fatal dose. It was also found that by previous stimulation of the heart by the administration of a dose of ouabain (so-called crystalline strophanthin) they could then adminster doses of the local anesthetics up to twice the average fatal dose, and by employing artificial respiration to tide over the period of respiratory paralysis the cats usually survived doses of the anesthetics up to one and three-quarters the average fatal dose. The close analogies between the behavior of man and cats to toxic doses of the local anesthetics and the fact that man also recovered promptly from the effects of nonfatal doses makes it seem highly probable that the use of epinephrin and artificial respiration will prove effective as a resuscitative measure in many cases of acute poisoning in man. In order to diminish the likelihood of intoxication from the subcutaneous injection of local anesthetics, especially those of Group 1, in man, epinephrin should be added to their solution as a routine.

4. Urobilin and Urobiligen of Stool and Urine in Pernicious Anemia.—G. H. Hansmann and C. P. Howard have studied 27 cases of pernicious anemia, and, as pathological controls, nine miscellaneous conditions. The method employed was a modification of the Wilbur and Addis spectroscopic method. The 27 cases of pernicious anemia were divided into four groups, according to the degree of anemia as determined by the total red cells count. Their observations lead them to conclude that the evidence of abnormal hemolysis occurs first in the stools, second, in the duodenal contents, and lastly in the urine. An increase of the urobilin and urobiligen in the urine and stools above 12,000 dilutions is a constant finding in pernicious anemia during the period of remission. The presence of even small amounts of uribilogen in the urine is evidence of a probable pernicious anemia during the period of remission. A low red cell count with a low urobilin and urobilogen count indicates an arrest of the activity of the disease process and a period of improvement may be anticipated. On the other hand, a high red cell count with a high urobilin-urobiligen content indicates a marked hemolysis, and often precedes a steadily falling blood pressure, as was demonstrated also by Robertson and McCrudden.

5. Broncho-spirochaetosis in Egypt. Najib Farah.
6. Foreign Bodies in the Esophagus and Respiratory Passages. Concluded. Irwin Moore.

1. Theories on Cardiac Massage as a Means of Resuscitation.—Lionel E. C. Norbury reviews the experimental basis and the theories in regard to the way in which cardiac massage acts, and discusses the methods employed. He concludes that in cardiac massage we have a very important adjunct to the methods of resuscitation, applicable in cases of heart failure during surgical operations, as also in certain other conditions, as cases of primary arrest of the heart in a condition of acute dilatation from poisoning by an overdose of a powerful volatile drug, such as chloroform; cases in which the gradual accululation of a volatile poison, such as chloroform, leads to primary paralysis of the respiratory and vasomotor centers, followed by stoppage of the heart; cases of asphyxia; cases of paralysis of the vital centers from exhaustion or injury, followed by stoppage of the heart. With stoppage of the heart during abdominal operation no time should be lost before starting subdiaphragmatic massage, and valuable time should not be wasted in the administration of drugs. Artificial respiration and cardiac massage should be carried out simultaneously. In such circumstances a very few compressions will usually reestablish the beat. If heart massage is contemplated it should be commenced within five minutes of cardiac arrest.

The writer says that personally he is inclined to resort to cardiac massage after giving other methods a trial of two minutes. It may be necessary to continue rhythmical contractions of the heart for several minutes before spontaneous contraction occurs, and to continue artificial respiration for some minutes after the heart beat has been restored. In obstinate cases means should be adopted for raising the blood pressure, either by pressure on the abdominal aorta, bandaging the extremities, or the application of Crile's pneumatic suit if that be available. Intravenous infusion of weak solutions of adrenalin in normal saline is also very efficacious, and is especially applicable in cases in which intravenous infusion with saline has already been started before the heart stopped, when adrenalin can be quickly added to the solution. In cases in which an intravenous infusion is not being already carried out this may be done quickly by using the internal saphenous vein, since the arms will be wanted for performing artificial respiration, or, as an alternative, the common carotid artery may be exposed in the neck, and a weak solution of adrenalin in normal saline solution be forcibly injected toward the heart by means of a syringe with a fine needle attached. Injection of adrenalin solution into the heart cavities or wall is liable to set up fibrillary twitchings, and is of no value in restoring normal cardiac contractions. The writer insists that one should never give up a case of apparent death under an anesthetic as hopeless until cardiac massage and its various accessories, as well as the other usual methods of resuscitation, have been given a fair trial.

2. Preliminary Report on the Intravenous Injection of Antimony in Filariasis.—Leonard Rogers reports his experiments in the treatment of filiarsis by the intravenous injection of soluble antimony salts at Puri in Orissa, where the disease is extremely common. Ten cases of filariasis received from five to eleven injections, only two to six of which were full doses of 5 c.c. of a 2 per cent. solution of sodium antimonium tartarate, and two cases received 1 to 500 colloid antimony sulphide, which was used in preference to tartar emetic as it is less toxic. In the case of both preparations the first dose was usually 2½ to 3 c.c., and increased by ½ c.c. at each injection until the maximum of 5 c.c. was reached. The injections were made daily for eight days, when the patients remained under observation sufficiently long, and then every other day. The writer concludes that all that can be said at the present is that repeated intravenous injections of safe doses of sodium antimony tartrate appear to produce a definite diminution of the number of filarial embryos in the peripheral blood, which is probably due to the direct toxic effect on the embryos in view of the great decrease in the activity of their movements observed just prior to a rapid diminution in their numbers. Whether the treatment has any effect on the adult worms in the lymphatics or on the symptoms of the disease remains undecided, but Rogers says that the data which he has so far been able to obtain are sufficiently encouraging to make it advisable to continue the observations.

7. Some Danger Signals in Cardiovascular Disease. James Third.

7. Some Danger Signals in Cardiovascular Disease.—James Third calls attention to a few outstanding signs and symptoms in cardiovascular disease that spell danger, and says that when we recognize these the meaning of all the others can be worked out and the disability fairly assessed. Myocardial degeneration, if we exclude that due to acute infections, is not likely to be present before middle life. Failure of compensation, or better, heart failure with congestion, is always the result of a myocardial change. When strain on the cardiac muscle goes beyond its physiological capacity then no matter what may be the condition of the valves, the heart as a whole is forced to run up a signal of distress. The first signal is usually breathlessness. The writer discusses two fundamental causes of breathlessness, acidosis and diminished vital capacity of the lungs, and states that whatever may turn out to be the cause, the fact remains that breathlessness of purely cardiac origin is the most important subjective symptom of cardiac disease. When of purely cardiac origin it is always accompanied by a general syanosis. It would be a mistake, however, to conclude that no form of heart disease exists when this symptom is absent. In the early stages of both mitral stenosis and aortic disease, breathlessness is usually absent. If we exclude the breathlessness of the neuroses, the severe anemias, lung disease, acute infections, and intrathoracic growths, then the degree of breathlessness, especially in a man past midday, is a fair measure of the cardiac inefficiency. The so-called "cardiac asthma" is always a serious affection. The condition occurs most frequently in elderly people with myocardial degeneration, high blood pressure, and sclerotic arteries. If accompanied with angina, or alternating pulse, the patient will not likely live more than a few months. True angina is no less serious. It is a signal of some degree of heart exhaustion. It may be interpreted as too much work, too much worry, or a lengthening of the shadows. Seeking confirmation of a diagnosis thus made by physical examination, it is generally agreed that serious myocardial change is accompanied by enlargement of the heart. The simplest and best guide to the size of the heart is position of the apex. The writer questions that refinement of diagnosis which states that a "heart is enlarged 1 cm. to the right" or "1 cm. to the left," believing that it is a physical impossibility to attain that degree of accuracy. The different murmurs are described and are said to have little prognostic significance in themselves. Mitral stenosis alone is usually, but not always, a serious condition. Mitral stenosis in the young accompanied by a presystolic and mid-diastolic murmur, and a definite thrill, is always a serious condition. The interval elapsing between the rheumatic or choreic attack and the development of the presystolic murmur is often a valuable guide to prognosis—the shorter the interval the more grave the prognosis, and vice-versa. Aortic disease is attributable to rheumatism or chorea in about half the writer's cases. Syphilis and arteriosclerosis claim the other half. After puberty the endocarditis variety or aortic insufficiency is consistent with good health for years, because the valve changes are not necessarily progressive. On the other hand, the degenerative form, usually syphilitic (and the war has taught us how common this variety is) is always serious. The value of the sphygmomanometer in diagnosis and prognosis is great, but not as great as some would have us believe. Blood pressure alone should never be taken as a basis for either diagnosis, prognosis, or treatment. It should always be considered in relation to the arteries, the size and exercise tolerance of the heart, and the condition of the kidneys. In all patients with high blood pressure the urine should be carefully examined.

La Riforma Medica.

September 13, 1919.

Pluriglandular Syndrome.—Fiei reports the following case: The patient is a woman whose looks and age correspond, she being 33. The adipose layer is well developed and properly distributed for her sex. The skin is pale, with some anomalies of pigmentation such as slight melanodermis of the backs of the hands and freckling in certain areas of the face. The scars of the surface were all pigmented and even the mucose of the lips. The scalp hair was not well developed and this is true also of the axillary and public hair. The breast glands, as distinguished from the mammary fat, did not exist. The eyes were small, hands very small, with tapering fingers. The blood pressure was low and with Pachon's instrument showed a maximum of 70-80, and a minimum of 40-30. There was marked physical and mental prostration. The woman had borne two children, but her internal genitals were hypoplastic. An *x*-ray showed a small sella. Adrenaline injected, 5 drops of a 1/1000 solution, showed increase of blood pressure from 75 to 100 Pachon in 2½ hours. The reaction would therefore be termed sluggish. The reaction to pituitrin was totally lacking, and this is true also of ovarian and thyroid extracts, neither of which caused either subjective or objective disturbance. The atropine reaction was diserete, while that to pilocarpine was intense. A blister was followed by marked pigmentation. While there is no mention of Sergent's white line, there were numerous evidences of hypoadrenalism such as the tendency to pigmentation, asthenia, and low blood pressure, and certain digestive disturbances. The fact that there had been no menstruation in the past three years, with the undeveloped genitals and secondary sex characteristics, pointed to ovarian insufficiency, despite the earlier history of child bearing. The type of obesity is grouped as ovarian, although there were also evidences of pituitary insufficiency in the hands and elsewhere.

Norsk Magazin for Laegevidenskaben.

September, 1919.

Pseudoascites.—Johannessen refers to a condition which begins in rachitic children during the first three years of life. The impression from seeing these children is that they are suffering from tuberculous peritonitis. Upon examination it is learned that the swelling is due to distention of the relaxed intestinal wall. The condition was described by Tobler of Breslau in 1915, but his knowledge of it goes back much further, he having made studies of it as far back as 1904 under Professor Vierordt. He reports four cases, all of which had been diagnosticated tuberculous peritonitis by internists. The patients were laparotomized under this diagnosis, and the error learned. The author relates a case of his own in a child 7 years old, believed to suffer from Hirschsprung's disease. He began to suffer from diarrhea and intestinal distension when aged 4 years. One year later the diagnosis was made of tuberculous peritonitis. The picture, however, changed in time to that of megacolon. When first seen by the author the general condition was cachectic. The abdomen was greatly distended, with obliteration of the navel. The girth was 61 cm. No tumor was palpable. There was a crescentic area of percussion dulness and a sense of fluctuation. The picture suggested a fermentation dyspepsia and enteritis. The patient was put upon an antifermentative diet, following which there was some improvement, and the girth was reduced to 55 cm. The presence of the fluid wave which was constant suggested that tuberculous peritonitis must also be present, and tuberculin tests were used with purely negative results. Blood count negative, likewise stomach content analysis. In the meantime, under oil enemata, the bowels were kept open and the girth came down to 49 cm. An *x*-ray was now taken, and showed no anomalies in the stomach or small intestine. The colon did not show any pathology which explained the symptoms. It was decided that the sense of fluctuation came from the fluid contents of the intestine which accumulated to the extent of a quart or more.

Book Reviews.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. XXXVI. Edited by JOHN F. BINNIE, M. D., Recorder of the Association. Philadelphia: William J. Doran, 1918.

THIS volume of the Transactions covers the papers read before the Association at the meeting held June 6, 7, and 8, 1918. There are the usual lists of present and deceased Fellows and Officers of the Association; obituary notices of Fellows who had died since the previous Annual Meeting, including Louis McLane Tiffany, George Ben Johnston, John B Murphy and William Joseph Hearn; the Address of the President, Thomas W. Huntington; the Report of the Fracture Committee and the full text of the forty-three papers on a wide variety of subjects. As usual, the papers are of a high standard of excellence; and the book forms a very valuable addition to the progressive surgeon's library.

MILK. By PAUL G. HEINMAN, Ph.D., Director of the Laboratories of the United States Standard Serum Company, Woodworth, Kenosha County, Wisconsin. Philadelphia and London. W. B. Saunders Company, 1919.

DURING a period of thirteen years the author of this work gave a course on milk in the University of Chicago. This course was associated with lectures on biology and bacteriology and methods of producing, handling and distributing milk. In view of this fact it is perhaps not surprising that he was able to write a book of nearly seven hundred pages on milk and then say that he "does not claim that the subject has been exhaustively treated." As a matter of fact it is difficult to find anything that has been left out. The sanitarian, the physician, the dairyman, the laboratory worker, the dietitian and the student will each find in this book the answer to the questions which he wished to ask about milk. It is profusely illustrated and is very easy reading. The author is of the opinion that the relation of the milk supply to epidemics of streptococcus sore throat is one of innocent carrier, the milk probably being infected by the handlers rather than the cow. There is a brief chapter on infant feeding. It is altogether a wonderfully complete work and will probably remain for a long time the principal work of reference on this subject.

THE OPERATIONS OF OBSTETRICS. Embracing the surgical Procedure and Management of the More Serious Complications. By FREDERICK ELMER LEAVITT, M. D., Formerly Assistant Professor of Obstetrics and Gynecology, University of Minnesota; Obstetrician to the City and County Hospital, The St. Paul Hospital, The Bethesda Hospital, etc., St. Paul, Minnesota. Pp. 466, with 248 illustrations. St. Louis: C. V. Mosby Company, 1919.

THIS book claims to present the subject of obstetrics from the operator's point of view, only enough pathology and physiology being introduced to give reason for an insight into the various surgical procedures. The author states that while much of the material has been gathered from personal experience, the work represents, for the most part, the cumulative knowledge of many teachers and writers. The illustrations are all from drawings by the author or Mr. George M. Ericson; but many are copied from other works. After reviewing the book rather carefully we should say that the work is very largely based on the work of others; for we find comparatively little strictly original matter.

The book is divided into two parts: Part I, of 286 pages, covering surgical procedures, while Part II, of 180 pages, discusses the management of the more serious complications of pregnancy and the puerperium. The usual obstetric operations—the induction of abortion and of pregnancy at or near term, the application of low and high forceps, version, breech extraction, Cesarean section, etc.—are well described and illustrated. The serious complications, such as eclampsia, postpartum hemorrhage, rupture of the uterus, prolapse of the umbilical cord, etc., are concisely covered.

While there is little that has not been as well covered in many of the well-known text books, this book should appeal to busy practitioners because of the clear and concise way in which the various subjects are handled, the excellence of the illustrations, and the unusually good index, which makes reference to any desired subject easy and satisfactory.

CHRONIC TRAUMATIC OSTEOMYELITIS; ITS PATHOLOGY AND TREATMENT. By J. RENFREW WHITE, M.B. (N.Z.), F. R. C. S. Formerly Resident Surgical Officer, Royal National Orthopedic Hospital, London; Formerly Surgeon, Tooting Military Orthopedic Hospital; Orthopedic Surgeon, New Zealand Forces. Octave of 144 pages, with 24 plates and 13 diagrams. New York: Paul B. Hoeber, 1919.

WHILE the average surgical patient can confidently look forward to cure after a much dreaded operation, White calls attention to the fact that in these chronic osteomyelitis cases neither the surgeon nor the patient can feel positive that one or even several operations will effect a cure, and that the patient may not have a recrudescence of infection even after long periods of quiescence. As White well says: "The occurrence of such postoperative recrudescence, by no means unknown even after the lapse of an apparently safe and prolonged period of waiting—and never so severe as when it takes the form of a return of osteomyelitis—constitutes for the surgeon a source of great anxiety, for the patient a calamity, always serious and often dangerous, loss of limb and even of life being the not infrequent consequences."

In this serious frame of mind the author approaches his task. In the course of the book the physiology of bone, pathology of compound fractures and chronic traumatic osteomyelitis, the examination of such cases, their clinical course, general principles and details of treatment are well covered; and, in addition, a number of illustrative cases are detailed and discussed. When and how to operate and proper methods of treatment before and after operation are thoroughly covered; and the entire subject is treated on a scientific yet eminently practical basis. White has written a book that should be of the greatest help to those interested either as attending physician or operating surgeon in traumatic osteomyelitis cases.

EIGHTH REPORT OF THE MICROBIOLOGICAL LABORATORY (Government Bureau of Microbiology) for the Year 1917. Being Part V of the Report of the Director-General of Public Health, New South Wales, for the Year ended 31st December, 1917.

THIS report, a bulky work of nearly 140 quarto pages, is devoted almost entirely to an investigation of the Australian epidemics an an acute polio-encephalomyelitis which was quite commonly known as "X disease." It includes extensive clinical, pathological and epidemiological studies and the protocols of numerous animal experiments, upon monkeys, sheep and horses especially. These researches seem to show that this disease was not associated or connected with the ordinarily known infantile paralysis and were unsuccessful in so far as the demonstration of the causative organism was concerned. The disease was transmitted to animals by intracerebral inoculation and appeared to be a definite clinical entity. The report is a very thorough and well-planned piece of work.

DISEASES OF THE EAR IN SCHOOL CHILDREN. An Essay on the Prevention of Deafness. By JAMES KERR LOVE, M.D., F.R.F.P.S.G., Lecturer on Diseases of the Ear, University of Glasgow; Aural Surgeon, Glasgow Royal Infirmary; Aurist to the Glasgow Institution for the Deaf and Dumb, etc., etc. New York: William Wood and Company, 1919.

THIS little work of ninety-four pages, contains much information on deafness in those of school age with special reference to such causal factors as the exanthemata, enlarged tonsils and adenoids and hereditary syphilis. Deafness due to ear disease proper, and deafmutism when hereditary, receive full consideration. The latter is shown to be a recessive Mendelian quality. The author coins an axiom "nearly all deafness is due either to infectious disease or wrong marrying." Therefore, eventually deafness must decline, to that extent at least; because both causal factors may be ranked as preventable.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DISTRICT BRANCH.

Thirteenth Annual Meeting Held in Yonkers, October 15, 1919.

THE PRESIDENT, JOSEPH B. HULETT OF MIDDLETOWN, IN THE CHAIR.

(*Concluded from page 646.*)

Some Problems Concerning Renal and Ureteral Stone.—Dr. EDWARD L. KEYES, JR., of New York said that the most interesting point in reference to stone in the kidney and ureter, whether we happened to be victims of the condition ourselves or were concerned in relieving our patients, was the treatment of renal colic. Kidney colic was a pain of varying degrees of severity, but frequently severe enough to require morphine, located in the loins at a point back of the midaxillary line. Such a pain in the majority of instances was due to distention of the kidney caused by a stoppage of the ureter, usually by stone. However, distension and stoppage of the ureter might result from a variety of conditions. It might result from mobility of the kidney causing angulation of the ureter. He had also seen kidney colic from the passage of urinary crystals. He had seen a child seven years of age with a complete anuria from such a collection of crystals. So there were a number of conditions that might simulate colic due to stone, but assuming that one had proven kidney colic due to stone, the question came up "What should be done right away?" Should we use the hot-water bag, codeine, bromides, etc., or should we use generous doses of morphine? The speaker believed there were advantages in giving large doses of morphine or even resorting to "obstetrical" anesthesia. He believed this the proper course to pursue, not only because it secured relief from pain but also as an aid in eliminating the obstruction. Intense pain meant spasm as little profitable in delivering the stone as a cramp in the leg. He had operated several times for the purpose of draining the kidney as a life saving measure in the presence of calculus anuria, and had had the pleasure of seeing the stone passed spontaneously and painlessly a little later. He cited an instance in which he operated because of rupture of the pelvis of a pyonephrotic kidney, the result of obstruction due to stone, and in this instance, though the stone was one inch in diameter, it passed painlessly into the bladder; the only difficulty was in passing it through the urethra. He had had similar experiences where, when the pressure was removed from above, the stones had passed silently. Hence he believed it an advantage to give morphine not only to relieve pain but to help the passage of the stone. In the second place, he had found that he could sometimes help the patient pass the stone by bimanual manipulation per rectum. This seemed a somewhat vague procedure, but it had yielded rather brilliant results in his hands. In a woman who had had one kidney removed and was in no condition to withstand an operation, he found the stone in the lower part of the ureter of the remaining kidney and by means of bimanual manipulation the stone was passed into the bladder within six hours. In several other cases he had been equally successful with this method. He felt inclined to prefer this method to the injection of oil into the ureter or the introduction of instruments into the ureter to reach the stone, as he felt that it was less likely to cause injury to the ureter. If a patient with an attack of renal colic had had a former attack and passed all the stone, without damage to the kidney or ureter, it was presumptive evidence that the drainage of the kidney was good and it might be expected that he would be equally successful in passing the stone that was causing the present attack of renal colic. This seemed to be borne out by an aphorism of Dr. Cole's that "large stones were silent." The silent stone grew large because it formed in the pelvis of a kidney in which the drainage was not good and it gradually took the form of the cavity in which it formed and did not cause colic. In reference to bilateral stones, one should not take for granted that the stone causing the colic was the only stone present. One might find that the stone in the ureter was not the only stone, but that there was a more threatening stone in the calyx of the other kidney. A patient with bilateral calculi was in imminent danger. If there was a stone in both kidneys the symptoms might be obscure and misleading. The speaker said he had seen a patient only the day before whose only symptoms of stone were loss of weight, pain in the epigastrium, repeated attacks of vomiting, vomiting of blood, and blood in the stools. The *x*-ray in this case showed stone in both kidneys. Test of the renal function showed both kidneys infected and working badly. He also cited other cases. The *x*-ray in diagnosis was a very fallible guide. The experienced roentgenologist had learned enough not to be misguided in most instances, but the best of them would be fooled occasionally. Diagnosis of kidney stone required ureteral catheterization and also injection of some such substance as sodium bromide or thorium, for pyelography or by Dr. Bugbee's method, or the use of a wax-tipped catheter. The wax-tipped catheter could be passed through the cystoscope just as any other catheter, and one could learn to recognize the flat scratch of the cystoscope in contradistinction to the claw-like tear caused by a stone. The wax-tipped catheter should be employed as a routine, for we never know when we might encounter an unsuspected stone. Routine pyelography would also show many unsuspected details. The pyelography should be performed upon one kidney at a time and always with the patient in hospital.

Dr. J. FIELDING BLACK of White Plains said that Dr. Keyes had told them his methods of getting the stone without operation and his methods of diagnosis. He would like to ask whether he had tried to use an instrument with a metal tip that passed through the cystoscope and was connected with the ear so that one could hear if the metal tip came into contact with a stone. With reference to passing a wax-tipped catheter, he would like to know whether Dr. Keyes had tried covering the wax tip with Cargile membrane which would be loosened when it got into the water in the bladder, and the wax-tipped catheter could thus be kept free from scratches by the cystoscope. He would also like to know whether Dr. Keyes had had any experience in passing a catheter with a small capsule on the end which would be dissolved in the fluid in the bladder.

Dr. HENRY DAWSON FURNISS of New York questioned the reliability of the wax-tipped catheter as a means of making a diagnosis of the presence of a stone in the ureter. He thought that one reason we often missed the scratch mark on the wax-tipped catheter was because when a stone had been in the ureter for a time the ureter became dilated and sometimes sufficiently to permit the catheter to pass the stone without enough friction to produce a scratch. It was a fact that in many cases of stone in the ureter one failed to experience obstruction to the catheter, because the stone if not tightly lodged was lifted from its seat in the ureter by the tip of the catheter. Another point in connection with the fact that the largest stones did not cause symptoms was that one got ureteral colic only when there was obstruction, and a stone caused obstruction only when it came into the ureter. In cases in which there had been prolonged renal colic one should not dally too long with palliative measures. The operation for the removal of a stone in the ureter was not serious unless it was complicated with infection due to retention. Early operation was indicated unless one got prompt results from palliative measures.

Dr. KEYES, in reply to the question "just how much morphine one could safely give in a case of renal colic inasmuch as they had been taught that large doses of morphine might aggravate toxic symptoms," said he had no particular formula as to the amount; he tried to give enough to relieve the pain. He did not think the presence of pain made a great deal of difference in respect to the toxic effect of morphine. There was a tradition against the giving of morphine for fear it would cause suppression of urine and uremia. He had given morphine just before making a cystoscopic examination and had watched the effect on the amount

of urinary secretion. During the fifteen minutes in which the cystoscopic examination was being made he had seen a slowing down of the secretion apparently due to the morphine, and then he had seen it increase. He felt that the danger from the toxic effects of morphine was very slight and believed in giving generous doses. As to the use of the metal catheter, which registered the presence of a stone by the conduction of the sound produced when the metal came into contact with the stone, he had possessed a metal catheter for ten years but had never used it. He did not think the covering of the wax-tipped catheter with Cargile membrane would prevent scratching. He had also heard of the use of a capsule over the tip of the catheter, but he did not feel that these devices were always a sure protection against scratching, and since one might always get a scratch it was much safer to differentiate the instrumental scratch from the stone scratch.

A Plea for Greater Care in Hand Surgery.—Dr. J. FIELDING BLACK of White Plains read this paper in which he considered the more serious hand infections, namely, those involving the synovial sheaths of tendons, the bursæ, and some forms of lymphanigitis, confining himself to the anatomy and diagnosis. He said he thought he was right when he said that very little attention had been paid to the surgery of the hand until we were presented with that wonderful work by Kanavel. It was not pleasant to think of the aimless way in which we went to work on infected hands—the short cursory examinations we made, the boldfaced lack of knowledge of the anatomy of the spaces, the haphazard incisions, the slashing of the dorsum, those terrible through and through gauze drains, and those terrorizing deformities that capped the end results. Now we had works that showed the precise anatomy of the sheaths, bursæ, and spaces, the mode of extension of pus from one locality to another, the method of making often precise diagnosis, all of which led to the proper surgical indication and procedure in any given case. There was now no excuse for general practitioners or general surgeons doing bad work on the hand. The writer described the anatomy of the tendon sheaths of the index, ring, and middle fingers, the radial bursæ, the ulnar bursæ, the middle palmar space, and the thenar space. In discussing the spread of infection, he stated that it was assumed that infection had taken place in a tendon sheath either by direct implantation or by the lymphatic stream. Extension from one sheath to another was by the lumbrical spaces or fascial space abscess. Spread of an infection from the little finger to the ulnar bursa and then to the radial bursa was frequent. The lumbrical spaces could spread the infection to the middle palmar space and from the middle palmar space back along the lumbrical canals. A middle palmar infection could spread to the thenar only in neglected cases. Infection could spread from the index sheath to the thenar space. Rupture of the proximal end of the index sheath would allow the pus to surround the tendon and lumbrical muscle. It would run along the lumbrical muscle and rupture through the sheet that separated this muscle from the thenar space. Infection of the middle palmar and thenar spaces was usually secondary. Infection might spread from the thumb sheath along the sheath of the flexor longus pollicis to the radial bursa and from there to the forearm under the flexor tendons. Radial and ulnar bursæ might rupture into each other in the forearm. Pus ruptures through the indefinite connective tissues separating the middle finger from the middle palmar space and entered the middle palmar space. Pus spread from the ring finger to the middle palmar space. Pus from the little finger sheath could invade the middle palmar space by its lumbrical muscles. Pus from the thenar space usually came to the surface on the dorsum between the thumb and index finger. The aim should be to make the diagnosis as early as possible. In making a diagnosis as to the position of pus in the hand one was aided by the knowledge that 90 per cent. of hand abscesses were on the palmar surface. History taking was of great importance. One must know where on the hand or fingers the injury was received, how it was received, what caused it, etc. In making the inspection it was important to note the patient's general condition, temperature, pulse, and respiration; the attitude of the hand and fingers, since in tenosynovitis the fingers were rigidly flexed, and if the infection spread to the forearm by the radial or ulnar bursæ the hand would be flexed at the wrist; the color, since infected areas were bright red in early cases and might be purplish or pale later; the area of greatest swelling, since the tendon sheaths were involved the fingers would be greatly swollen, though the swelling might not be limited to the site of involvement; the shape of the palm, since in palmar abscess the shape of the palm was obliterated and often the thenar area was edematous. If the thenar space was involved the parts ballooned out and the thumb was pushed away outward. Should the radial or ulnar bursa be involved, a swelling existed above or proximal to the annular ligament, and a fulness was noted on the radial or ulnar side of the hand. It should be emphasized that the area of greatest swelling did not always denote the site of the pus, as usually the dorsum was greatly swollen and there was edema of the loose connective tissue, which in the past had been responsible for many errors in treatment. We should also remember that close on 90 per cent. of hand infections, affecting the tendon sheaths, were on the palmar surface. The method of examining the hand was of great importance. The expert abdominal man had a feather-like touch; he pressed just hard enough to reach through the fat and touch muscle. The same delicacy of touch was necessary in hand diagnosis. One should examine for: (1) tenderness over the sheath, outlining its limitations; (2) for rigidity of the flexed fingers and wrist, and (3) for induration, as against mere edema. For tenderness, palpation should be done gently and systematically from the distal end of the sheath, noting the degree and limitations. In the index, middle, and ring fingers, the swelling and tenderness might be limited to the distal end of the palm, unless a ruptured sheath obscured the picture. In the thumb and little fingers, if their respective bursæ had been involved, the tenderness reached up the course of these and pressure above the wrist caused pain. The wrist was flexed and the lower end of the forearm became indurated, red, and swollen. On account of the juxtaposition of these two bursæ under the annular ligament, any involvement of the ulnar bursæ might cause pain and rigidity of the thumb and vice versa. Should the thenar space or middle palmar space be the seat of pus, the tenderness and swelling should be limited to these areas, but the fingers whose tendon sheaths were in contact with whichever space was involved would be flexed and rigid, but to a less degree than in tenosynovitis. Many times a massive edema and redness, though soft and pitting, were mistaken for the inflammatory infiltration of infection, and consequently many unnecessary cuts were made in uninfected areas. Mediocre knowledge led to misplaced incisions, infecting healthy areas, to incisions too short or too long, to incisions that cut nerves or important vessels, with the result that we got deformed and functionless hands, often with ankylosed joints, amputated fingers, or contracting scar tissue, that made the hands resemble claws, to say nothing of prolonged convalescence, economic loss, and even death for the patient.

Dr. CHARLES OGILVY of New York expressed the opinion that this paper was quite apropos at this time, as we had learned what was meant by final results, and inasmuch as good final results were not demanded of us. It was unfortunate that so often these cases did not come to the surgeon until two or three months after the injury, when a deformity had already resulted. In such cases one could often get a great deal from the history that he could not get from the examination. If he would then follow up the history by an *x*-ray examination he would often find a splinter of bone or a fracture that had been overlooked. It often happened that the primary injury caused less harm than the operator. Dr. Ogilvy made a plea for early active and passive motion in all infected hands. Early active and passive motion would prevent a great many contractures and deformities, and would obviate the necessity for a subsequent operation in many cases.

A Discussion of the Submucous Resection of the Nasal Septum.—Dr. W. MEDDAUGH DUNNING of New York presented this paper, in which he stated that the

submucous resection of the nasal septum to correct deviation had become the recognized operation. The nasal septum was seldom perfectly straight, but usually presented deviations from the median line, and was also the seat of thickening and spurs. If these did not cause any interference with the breathing or drainage from the sinuses they were of little importance, but when they did cause trouble they demanded surgical interference. The chief indication for submucous operation was in those cases in which there was nasal obstruction to such an extent that the patient suffered and his health was seriously impaired. The writer also emphasized the importance of the operation for asthma and hay fever in many cases. How frequent nasal deviations were might be judged when we read that out of 4,000 cases examined in one of our hospitals in one year there were 3,823 septal deformities, most of them being deviations. Deviations of the septum were a peculiar characteristic of the Caucasian race. It was estimated that about 30 per cent. of white men had septal deviations, and they were more often to the left than to the right. In speaking of the deviated nasal septum, one generally meant one which was pathological or obstructive. Nasal septum deviations were usually due to some form of traumatism that had occurred early in life, and were more frequent in men than in women on account of the sports indulged in by boys early in life. Mouth breathing might also be a cause, and bowed deviations were the common sequelæ of high arched palates. Submucous resection was done with the aid of reflected light. The instruments used were a speculum, small scalpel, a combination curette elevator, Ballinger swivel knife, punch forceps, small chisel, and a mallet. With the patient seated, the nose was cleansed, anesthized, and rendered nearly bloodless by packing with cotton saturated with a solution composed of about equal parts of cocaine, 10 per cent., and adrenalin chloride 1-1000. A small piece of cotton thoroughly saturated with the above solution was gently inserted in the region of the superior turbinate or the highest part of the nose. The next cotton application was a little larger and inserted above the lower turbinate, and the third application was much larger and longer and was inserted below the lower turbinate, well back toward the pharynx. After remaining in position about twenty minutes it was removed and a vertical incision was made anterior to the white line. The knife was inserted about one-third of an inch, in most cases from the top of the nose, and brought downward to the floor and the outside of the nose. In the nose, incision was made through the mucous membrane and the perichondrium, but not into the cartilage. The mucous membrane was then elevated starting at the highest angle of the incision, pushing the elevator gently backward and downward, and then bringing it forward. In most cases one was able to separate the mucous membrane from the cartilage from behind forward and then, scraping through the cartilage, to separate the mucous membrane from the other side. The cartilage was then removed with a Ballinger knife or forceps. If the deformity was not corrected it was advisable to insert cutting forceps and bite through the junction of the perpendicular plate of the ethmoid with the cartilage. If one was careful at this point there was practically no danger of breaking the cribriform plate. Next the perpendicular plate of the ethmoid and the part of the vomer that might cause obstruction were removed. The incisor crest as a rule would form more or less obstruction and it was surrounded by a large amount of fibrous tissue. This tissue and the adherent membrane might be easily separated with a sharp knife, if one would remember to keep the edge of the knife on the incisor crest. The incisor crest was easily removed with a chisel and mallet. The incisor crest extended well forward and if the chisel was inserted well down on the crest and driven upward it would separate with very little force. After removing the incisor crest one would be surprised at the large opening in the nose between the membrane. The intermaxillary ridge, as a rule, was very thin below the junction of the triangular cartilage, and if the chisel was inserted at the thin part of the bone, with one or two little taps one was able to fracture the bone as a rule for a considerable distance posteriorly, and it was easily removed with a curette or forceps. The membrane was now divided at its outer angle for a distance of about one-third of an inch and replaced on the septum. The nares were packed with vaseline gauze which was removed at the end of twenty-four hours. A few crusts would form which were removed once a day. The patient was generally able to return to his usual occupation twenty-four hours after the packing had been removed. The advantages of the submucous resection over other operations for deflection were: (1) That no mucous membrane had been destroyed. (2) That spurs and deflections had been entirely removed with the thickening of the septum. (3) That the ridge of cartilage which was wedged in between the lateral cartilage had not been interfered with, and there was absolutely no danger of a falling or saddle-back nose.

The Delagenière Bone Graft.—Dr. Edwin G. Ramsdell of White Plains made this presentation, which he illustrated with lantern slides. He said that although Col. Delagenière had been using this method for several years, the greater number of his cases had been operated upon since the war. The writer had had the privilege of working with Col. Delagenière, of following his cases, and seeing the results. The type of cases treated by Delagenière might be divided into the following group: (1) Cranial defects. (2) Faciomaxillary cases. (3) Old fractures of the long bones with loss of substance, or non-union from other causes. (4) Flail and ankylosed joints. The method of obtaining the graft was the same for all cases. Having determined the size of the defect to be covered and the length of the graft to be obtained, a vertical incision was made over the center of the internal surface of the tibia and the skin dissected, exposing the internal surface and the anterior and internal borders of the tibia. The graft was now outlined by firmly incising the periosteum, the width and length of the graft being variable, but the thickness always the same, namely, about that of ten-cent piece. With a sharp chisel and mallet the graft was gradually elevated from the surface of the tibia. A chisel preferably one inch wide was used and with a little practice these grafts could be removed in a very few minutes, in much less time than was often consumed in adjusting an electric motor saw. The graft was flexible because it consisted of periosteum to which was attached, not a single piece of bone, but many small thin fragments or chips approximating the size of a finger nail. The graft could be moulded to suit the part to be grafted, as, for example, the convex surface of the cranium or the irregularly shaped inferior maxilla. The flexibility was also a great advantage in rebuilding, for example, a chin or angle of the jaw, or the head of a bone in the work on flail joints. The writer then described in detail the procedures employed in each of the groups of cases mentioned above. In cranial defects an eliptical incision was made with the idea of excising the scar, but the incision varies with each case, and in general it might be said that it followed the scar and was designed to excise as much cicatricial tissue as possible. The edges of the scalp were freely separated from the underlying pericranium. In dissecting the scar care was taken to avoid injury to the dura. The edges of the bony defect were then determined and the pericranium separated with a sharp periosteal elevator from the underlying bone. This was effected by making a small incision through the pericranium to bone on either side of the defect and working from side to side. The bed was now ready for the graft, and one of two methods might be used, depending on the size of the defect. In large defects a small graft was cut just large enough to fit into the opening, and this was placed periosteal surface toward the brain. Then on top of this one or two large grafts were placed, extending well out over the cranium under the pericranium, always with bony side against bone. If more than one graft was needed to cover the defect the edges were very slightly overlapped. As well as possible the pericranium was approximated with a few interrupted catgut sutures and the scalp nicely closed with interrupted silkworm gut. A small rubber drain was used but removed in forty-eight hours. As early as ten days after the operation these wounds were firmly united and the grafts fairly solid. After four or five weeks the only remaining evidence of the former defect was the scalp scar. Out of 93 cases in this series there were 92 successful results. In one case the graft did

not take and was eliminated. Certain modifications of this technique were described which met the indications in various forms of faciomaxillary defects. There were 53 cases of interior maxillary grafts, 45 of which gave excellent results. There were three partial successes on account of elimination of a portion of the graft and three incomplete results on account of infection due to the presence of hematoma. There were two failures, due to lack of co-operation on the part of the patient. There were 25 grafts applied for bony defects of the face other than these inferior maxillary cases, and of these 23 gave good results. Only two were incomplete as the result of infection and the development of fistula. The author stated that it was almost impossible to describe any one typical procedure for the group concerned with the reconstruction of long bones and hence described a few representative cases, one being a fracture of the humerus with loss of substance and pseudoarthrosis, another in which the entire ulna had been reformed by the use of osteoperiosteal grafts, and a third in which a useful elbow and wrist joint results from the reconstitution of the ulna. In the case of the forearm two grafts were usually used and placed in such a way that their bony surfaces were approximated throughout the entire length of the grafts, except at the ends where they were separated by the upper and lower extremities of the fractured fragments. In the fourth group, each case was a little different from the next, and the surgeon had to use his ingenuity in the best arrangement of the grafts to bring about a maximum restoration of normal conditions. In the groups of defects in the long bones and joints there were 83 cases, most of them being pseudoarthroses following gunshot wounds. Of these 83 cases 77 retained the grafts and gave satisfactory functional results. Three were partially successful, one eliminated the graft, and another developed pseudoarthrosis, necessitating a second operation. One died from chronic infection three months after operation. There were in all 254 cases, of which 237 were successful, 11 partially successful, 5 failures and 1 death.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixty-ninth Annual Meeting, Held at Harrisburg, Pa., September 22-25, 1919.

SECTION ON SURGERY.

First Day—Tuesday, September 23.

DR. DONALD GUTHRIE OF SAYRE, PA., IN THE CHAIR.

Chairman's Address: Hospital Morale.—Dr. DONALD GUTHRIE of Sayre, Pa., presented this address, saying that to maintain good hospital morale it was important to have the closest cooperation between the management of the hospital, the medical staff and the nursing force. The patient should be considered from a psychological standpoint from the time she was admitted until after she left the institution. During her entire stay her mental welfare and comfort should receive the same careful consideration as her physical welfare—for the majority of patients were mentally, as well as physically, ill. Good hospital morale demanded loyalty on the part of the nursing force and the medical staff to the chief on duty. Dissatisfaction on the part of the interns was extremely contagious and spread quickly from the training school to the patients. He believed if we were to give our interns more consideration and attention, if we were to go over our cases more carefully with them and ask them more often for their opinions and suggestions, we could make cheerful coworkers of them instead of dissatisfied critics. Good food, well cooked, served hot in an attractive way, was a great asset to the hospital. No convalescent should be allowed to be hungry, if there was no reason why the diet should be restricted. The surgical or medical chief should examine all patients when they were ready to leave the hospital. At that time the patient's disease or operation should be explained to her in detail, all final instructions for her after care should be carefully given her, besides telling her that her home physician would be written to about the case. This would give her a sense of security at home, and the request that she write back a report of herself from time to time was met with delight, for she would feel that the interest shown in her would not come to an end when she left.

Diagnosis and Treatment of Congenital Pyloric Stenosis.—Dr. ALBERT F. HARDT of Williamsport, Pa., read this paper, saying that the first symptom which attracted attention was vomiting, frequently beginning as a regurgitation which gradually became worse until it became distinctly projectile in character, the vomit often being projected several feet. It occurred after each feeding or after several retained feedings, and there was nothing distinctive about the character of the vomitus. Of all the symptoms, the vomiting was the most alarming. There was a peristaltic wave which appeared after food was taken, and radiated from the cardia to the pylorus. This was elicited by giving two or three ounces of food, and while the infant lay on its back in a favorable light for observation, the wave would appear. A tumor might be felt to the right and above the level of the umbilicus, usually a small movable mass. There were scanty stools and urine and progressive loss of weight. The scanty stools were, of course, due to the reduction of the amount of food reaching the bowel. The scanty urine was due to increased absorption of water. As regards the weight curve, it was interesting to note that it was not uncommon, following the initial loss of weight after birth, to have a steady though not marked upward curve. This, however, continued but a short time after vomiting began. It then became stationary and loss of weight became rapid. It was now generally agreed that only in the mildest cases with partial retention and no or little loss of weight should medical or expectant treatment be tried, but in all other cases operation should be advised at once. As regards mortality, a low mortality would depend upon early diagnosis and early operation; the longer the duration of the vomiting, the greater the surgical risk. Cases that had vomited over two weeks were usually in such poor physical condition that operative mortality would necessarily be high.

Dr. LEVI J. HAMMOND of Philadelphia said that at times the tumor could be felt in the region of the pylorus, though more often the liver, which was invariably enlarged to once or twice its natural size, so covered it over as to prevent its being palpated. In two of his cases, the tumor could certainly not be felt; in one it was doubtful; in the fourth it was distinctly felt. The peristaltic wave was typical in all. The other symptoms were those naturally to be expected and incident upon persistent vomiting, such as loss of flesh, progressive emaciation, exhaustion, subnormal temperature, and the classical picture of marasmus. As the condition was surgical from the onset, he considered that medical treatment should not be employed longer than was necessary to establish diagnosis. This applied alike when the cause was either persistent spasm or hypertrophy, for even though the obstruction were due alone to spasm (which was hardly conceivable), such patients died from inanition if the spasm was intense, prolonged and frequently recurrent, hence, under such circumstances, it was equally dangerous with hypertrophy. Within a few hours after operation had established free drainage, nourishment could be taken in small quantities, and increased to full feeding in three days. Surgical treatment should consist in either pyloroplasty or posterior gastroenterostomy; the former was indicated where the pathology was demonstrably localized. As this was not in his experience often possible, he had always elected posterior gastroenterostomy, which he believed would meet the greater number of indications. Early recognition of the precise nature of the condition and prompt operative treatment as indicated, before tissue-cell resistance had too greatly ebbed away, should result in recovery of at least 80 per cent of these patients.

Dr. JOHN J. GILBRIDE of Philadelphia said that congenital stenosis of the pylorus had a fairly definite symptomatology. Having a child with persistent vomiting in the presence of constipation, he thought that one might well suspect the presence of a stenosis of the pylorus, and the mere fact that the practitioner suspected such a condition led him a long way toward

making a correct diagnosis. In the cases he had seen relative to the Rammstedt operation the pylorus was in most instances rather hard and almost of a cartilaginous consistency, which increased the difficulty in carrying out that technique. One should be reasonably certain about the diagnosis before recommending operation, as operation on these little patients demanded a very caretul and painstaking technique in order that the lives of these frail individuals should not be needlessly sacrificed.

Fractures of the Pelvis.—Dr. SAMUEL P. MENGEL of Wilkes-Barre, Pa., read this paper, saying that there was no doubt that if *x*-ray examinations were routinely made in all doubtful cases, there would be found a greater number of fractures of the pelvis, and incidentally, fewer recorded deaths from internal injuries. Fractures involving the crest of the ilium, which, owing to its position was frequently exposed to trauma, were often of little moment, usually causing no great inconvenience, and were very rarely complicated. Fractures of the pubes and ischium, on the contrary, occurred more frequently, were often multiple and complicated, and had a high mortality. In a series of 69 cases admitted to the Wilkes-Barre Hospital during the past eight years, there was no mention made of fracture of the body of the ischium. Complications were numerous and often severe. Owing to the intensity of the fracturing force, in many of the cases the pelvis was crushed, with extensive damage to the soft parts. In this group of cases there were 46 that were complicated. The time requisite for a complete cure in these cases was directly proportionate to the extent of injury and the displacement of the bones. Too often these factors were not carefully weighed, and the patient was allowed out of bed and on his feet before bony union had occurred, with the result of increased deformity, or perhaps a cripple for life. He had in a number of instances seen cases with far greater deformity at the end of nine months or a year than they had had when discharged from the hospital. Suspected cases of ruptured bladder should have an exploratory laparotomy as early after the injury as possible. The one great factor of these cases was thorough drainage, and the earlier it was established, the better were the chances for recovery.

Dr. WILLIAM L. ESTES of South Bethlehem said that he wanted to emphasize the fact that these fractures of the pelvis occurred very much oftener than one would suppose. While it was true the nature of the work of miners and the various accidents of their trade brought about their injury perhaps oftener than in many others, it was a fact that in industrial establishments they also occurred very frequently and, if any case entered the hospital under the care of a surgeon with the symptoms which would suggest some injury about the pelvis, it was exceedingly important that he should have not only clinical examination, but he should always have a skiagraph. Case after case had passed through their hands in which they could not detect the fracture, which could be seen by a well-taken skiagraph, and he thought that was an exceedingly important method of pursuing the investigation.

Dr. JOHN B. ROBERTS of Philadelphia said that he had recently been called to see a patient, 78 years of age, who had been knocked down by an automobile. She had a paralysis of one side of the face and was violently shocked. She had fractures of both bones of one leg. *X*-ray examination showed fissures of the vault of the cranium running horizontally. There was a good deal of contusion, showing a blow about the hips. He suggested that an *x*-ray examination be made, although there was no trouble with the urine. The *x*-ray showed a fracture of the ramus of the right pubes and of the ischium. He was astonished to see how this old body got along, entirely different from the mortality described by these other gentlemen.

Surgical Observations of War Industrial Activities at the Methodist Episcopal Hospital, Philadelphia.—Dr. LEVI J. HAMMOND of Philadelphia said that serious injuries in industrial plants during the war became at once most formidable because of inadequate means on the part of the industrial plants to furnish even first-aid care. As proof of this, 738 patients suffering from infected wounds had been received at the hospital. The climate during the winter of 1917 had been most unfavorable, being throughout too cold to be compatible with work in low land, and, as a result, gangrene from frost-bite necessitated the amputation of the limbs. He thought that the energy of the laborer was, during this period, greater than ever before exhibited, each one, without murmur, enduring a greater amount of physical hardship than he would have tolerated under ordinary circumstances. Crushing injuries of the head, the pelvis, the thorax, the face, and extremities had been far more numerous than they would have been among an equal number of skilled laborers. For example, there had been 135 crushing injuries of the body, 53 of the brain, 28 of the pelvis, etc. Altogether there were 7,805 severe injuries treated at the Methodist Hospital from the beginning of the war until the beginning of 1919, entirely exclusive of the minor injuries. It had been necessary to amputate in 81 cases of fracture. The immediate mortality was high, there having been 87 deaths from all classes of injury during the period of the war activities.

Dr. WILLIAM P. WALKER of South Bethlehem said that in Bethlehem, at St. Luke's, he could echo what had been said about the number of cases. Fractures were numerous and they had had the various types and did not introduce anything new in the way of surgery. They gave a fair try-out to Dakin's solution, used by the drop method. Their fractures, excepting those of the femur, were treated by immobilization and plaster and they resorted to a good many plating operations.

Empyema.—Dr. J. STEWART RODMAN of Philadelphia said in the prewar days it had been the rule to see empyema cases drain for weeks and not uncommonly for months, necessitating drastic procedures later to obliterate the pus cavity which had formed. In this respect the newer methods of treatment were great steps in advance and it would be no less of a surgical triumph to put the patient back to a civilian occupation at the end of two or three weeks than it had been to return the soldier to duty in that length of time. It was his earnest conviction that this was entirely possible if we only remembered our war experience in treating empyema henceforth. He wished to outline his own experience in treating some 240 cases of empyema. He referred to the empyema caused by the *Streptococcus hæmolyticus* following in the wake of a violent epidemic of measles complicated by bronchopneumonia, in the epidemic of 1917 and 1918, during which in a little more than the three months of November, December, and January one-third of the command of the 36th Division, some 8,000 troops, suffered from measles. It was a most pernicious type of measles in that the complications of bronchopneumonia leading to empyema, mastoids, and other metastatic infections were common. The diagnosis was interesting and taxed the watchfulness of the medical side of the hospital. *X*-ray proved of great value in localizing early collections and those that became "walled off" later on. In the first group of 50 cases the plan had been followed of draining the chest cavity as quickly and in as simple a way as possible; thoracotomy without rib resection had been done, for the most part under local anesthesia, and drainage provided for with one rubber tube of large dimension. Often this was done in the ward, as it was not thought wise to attempt moving the patient to the operating room. The mortality in this first group was high and not a few died within several hours of the thoracotomy, enough, in fact, to lead to the belief that this plan of treatment, while apparently based on sound surgical principles and civil experience, was not the one best calculated to deal with this particular type of empyema. Accordingly, after the first 50 cases, it was decided to aspirate the worst cases, and they had found to their great relief that this procedure was a distinct advance in treatment. As the fluid was thin at first it was possible after diagnostic puncture had been done to remove by means of the Potain aspirator the greater part of the fluid. The improvement in the general condition, as a rule, was marked, the patients appearing less toxic and respiration becoming easier. Of course the chest cavity would soon fill up again and aspiration had to be repeated, usually after the lapse of three or four days. The patients also after several aspirations were in much better condition to withstand the shock of this more formidable procedure. The

surgical treatment of choice then became aspiration, late operation, and thoracotomy with rib resection. To this was added irrigation, after one week had elapsed, with physiological salt solution and later Dakin's solution. He confessed to having had a prejudice at that time against irrigating an acute empyema cavity, which he had entirely lost since.

Dr. A. Ralston Matheny of Pittsburg said that Dr. Rodman's paper gave a very good history of experience in the army hospitals. He based his remarks on cases at Camp Gordon, Atlanta, as well as at Camp Grant. At Camp Grant they had 83 cases; the first 50 cases were given the old-fashioned treatment and the mortality was 80 per cent. This procedure was stopped by the War Department. Orders were sent out not to operate because it had been found that they were up against a new type of empyema.

Dr. W. W. Babcock of Philadelphia said that for a while the medical men did not know what they were up against. The patients were taken ill usually after malaise and some exposure and died rapidly before anything was done. They were not treated by operation. A number of autopsies were made and the medical officer in charge pointed out that the cavities were filled with turbid fluid and the surgeons got busy. At the beginning of the epidemic when nothing was done every patient died, the mortality was about 100 per cent. Later on, when they began to do resections and drainage operations the mortality dropped to about 80 per cent. So the surgeons congratulated themselves and thought these results were due to those early operations. Then it went on to spring and the Empyema Commission got on the field and the mortality was reduced. The commission decided to observe the effect of treatment as opposed to no treatment. They had 27 or 28 cases and they held off and did aspiration and found that of these only one died.

Pulse Pressure in Traumatic Cerebral Compression.—Dr. Harry M. Armitage of Chester, Pa., read this paper, saying that in severe fractures of the base with widespread hemorrhage the blood pressure symptoms were valueless. In traumatic cerebral compression, where the local symptoms suggest a blood clot or a depressed fracture pressing on the brain as evidenced by *x*-ray, palpation or paralysis, the general symptoms such as slowed pulse and blood pressure findings might be of little value if the medulla was not involved by pressure. Operation was the only rational treatment in these cases. In cases with major symptoms of choked-disc, headache, disturbed sensorium, coma, increased pressure of the cerebrospinal fluid as registered by the spinal mercurial manometer, and slow pulse, there would invariably be found a high pulse pressure. The systolic pressure was too uncertain a factor to be of any value whatever in diagnosing the amount of pressure. Our decision as to whether a patient should be trephined should be determined after grave reflection and consideration of the entire group of symptoms, but in all cases of head injury frequent estimations of the pulse pressure and pulse rate should be made. The issue was unmistakable. The subject had passed out of the realm of thought and presented itself as a clean-cut fact. Where there was an increasing pulse pressure and a falling pulse in traumatic cerebral compression an operation should be performed without any delay.

Dr. Lyndon H. Landon of Pittsburgh said he dared to say that at least 80 per cent. of the cranial cases the surgeon was called upon to see were suffering from the effects of increased intracranial pressure, whatever the underlying lesion, and regardless of the necessity of relief from the subjective discomforts from which these patients suffered, the important feature for our consideration, especially in the acute cases, mostly resulting from trauma, was the alleviation of the interference which this increased tension imposed upon the proper functioning of the vital medullary centers. It was unfortunate that in so many of these cases procrastination seemed to be the order. Any means, therefore, of which we could avail ourselves in arriving at the proper line of action were most acceptable. Of course, in many of these cases our duty was unmistakable. It was in the borderline types that we needed finer diagnostic help, and he thought that Dr. Armitage's cases clearly showed the value of careful observations of the pulse pressure as a guide to the proper prognosis and treatment, especially the former. Personally, aside from and in conjunction with the general symptoms which should never be lost sight of, he had come to rely very largely upon the direct estimation of intracranial pressure by the spinal mercurial manometer. Frequently repeated this not only showed the exact pressure existing, whether it was increasing and to what extent, but by the lumbar puncture we procured the added information as to the presence or absence of blood, while the withdrawal of safe amounts of cerebrospinal fluid, guided by pressure readings, was often of distinct therapeutic value. The most important thing for us to remember in dealing with cerebral compression was not to postpone decompression until the intracranial pressure reached 40 mm. or 59 mm. of Hg., until the pulse pressure far exceeded the pulse rate and all the symptoms of Kocher's third stage had appeared. The time to consider operation was when there appeared signs of beginning compression. The utter futility of operating after compensation had become exhausted, as in the fourth stage of Kocher, should not need comment.

Dr. Charles H. Frazier of Philadelphia said that he would not take up time, as the hour was now late, were it not to subscribe to the statement which had been made by the reader of this paper, namely, that decision as to trephining should be determined after grave reflection and consideration of the entire group of symptoms, but in all cases of head injury frequent estimations of pulse pressure should be made. Those who fully followed the literature of the subject had seen articles appear from time to time in which the writers, many of them younger men, had laid great emphasis on the symptoms of pressure, rise of blood pressure and choked disk. It was his opinion that if one were to rely on these two objective symptoms as giving the indications for or against operation it would be done in many instances in which it should not have been done and would not be done in many instances where it should have been done. In determining the indications for or against operation, one had to take the whole clinical picture into consideration.

Second Day—Wednesday, September 24.

Self-Retaining Slide Bone Graft.—Dr. H. C. Masland of Philadelphia read this paper, in which he said that the open operation for fractures should be used only when the older standard methods did not promise a good result. His experiments, using a bone plate and bone screws and either a surface contact or a partial inlay on the fractured bone, gave a good mechanical result, and in selected cases should give a good final result. In plastic bone surgery the need of faultless aseptic surgery was absolute. This applied to the hands. It might be that a glove could be as sterile as an instrument, but, if the operator trained himself not to touch the bone with his hands, it would have a salutary effect on other details. All traumatism should be eliminated as much as possible. This could be accomplished best by a power-driven bone-cutting equipment. All the bone cutting necessary was done without force, with accurate control, and minimum wastage. The bone should be held as rigidly as possible. Absorbable sutures, which were the only kind recommended for this purpose, would stretch and allow play in the jointing. Where bone pegs alone were used and held by virtue of being forced in, the pressure might cause atrophy and lessen the vitality of the region involved. In this method the advantages were: the bones were brought into good alignment; there were no sutures to slip; no metallic material was present; the bone grafts could not slip; the strength of the graft plus its bracing was the index of the strength of the jointure; the requirements laid down for the greatest likelihood of regeneration and union were adhered to.

Dr. Walter Lathrop of Hazleton said that some two years or more ago he had reported a series of operations for fractures of long bones, especially the tibia, in which the sliding graft was the method of choice and this graft held in place by kangaroo tendon, as practised by Albee of New York. He had previously tried out the mehod of fastening the graft by means of autogenous bone pegs, made from one of the fragments and formed to fit by the dowel. This had not proved as useful as the kangaroo tendon, though pos-

sibly the bone screws, as described by Dr. Masland, might prove to be very satisfactory, but where time and asepsis counts for so much, he thought the use of the tendon sutures was an ideal method. The great point to remember was that the final or fixed dressing meant much to the surgeon, for the degree of immobility one got often determined the success of the graft.

Dr. FRANCIS P. BALL of Lock Haven said that in his experience in all those cases in which a metallic substance was introduced for the correction of fracture it sooner or later had to be taken out. In a recent conversation with Dr. Albee he was gratified to find that he confirmed his attitude in that matter. He believed that the coming, in fact the present, method of treating fractures where the open method was available, was by the bone graft. He believed, however, that a great many fractures could be treated without the open method if advantage were taken of common sense means of overcoming the deformity and frequent *x*-ray of the progress of the case. He did not believe that every case of fracture by any means needs an open method of treatment.

Dr. JOHN B. LOWMAN of Johnstown said that he was convinced that we would not operate nearly so much as we used to. As to the bone graft he thought that it had certain indications and they were more particularly in those cases of delayed union. During and since the war he had seen quite a few failures from bone graft. He believed that most of these failures were due to faulty technique. A great many of these cases of delayed union in the army were due to infections. They were operated on too soon and infection was stirred up. He did not think any of these cases of delayed union should be operated upon in less than three months. One should have a bone graft that would hold the fragments firmly so that they would not move and the ideal method was the inlay method of Albee. Another important factor was proper splinting. He thought all these cases should be put up so they would not move at all, preferably in plaster-of-paris.

Dr. HERBERT B. GIBBY of Wilkes-Barre said that he thought a great deal of stress should be laid on carefully putting up the fracture so that there would be as little motion as possible.

Symposium on Goiter: Thyroid Disease.—Dr. HENRY S. Plummer of Rochester, Minn., presented this paper in which he said that he felt perfectly confident now that he knew when a patient was cured from data, without seeing the patient. That came from certain laws of pulse pressure and pulse rate. At the time that he became interested in the subject there had been a feeling in the profession that there were various forms of toxemia associated with the thyroid that were not exophthalmic goiter. Wilson had reported in 1908 that about 20 per cent. of the supposed exophthalmic goiters did not have the characteristic picture of hypertrophy. In 1910 there had gradually dawned on his vision the fact that the adenomata did not belong to the exophthalmic series at all. Everyone had been making the mistake of calling cases of exophthalmic goiter hyperthyroidism. They were not. The exophthalmic goiter was seldom missed by relatively good men. Adenomata and hyperthyroid are constantly missed by the best men in this country because we have lots of circulatory troubles, myocardial, etc., that they attribute to myocardial degeneration, symptoms of essential hypertension. When there is a true hypertension due to adenoma and it is all but taking the patient's life, it yet does not suggest hyperthyroidism. In regard to metabolism, we all burned 39 calories to a square meter of body surface an hour when we were at rest. Normal people 12 hours after taking food burned at that rate. Now if there was thyroid gland and there was no thyroid in the tissues, one burned approximately 35 points below. He had had 36 cases of what we would call high-grade myxedema in the last year and a half, cases in which metabolism was below 30; the entire series had been cured as far as one could see with one hypodermic dose of thyroid. The metabolic rate in hyperthyroidism was high. So when we were dealing with goiter we were dealing with whether a person was burning food too fast or not, and the symptoms of exophthalmos were symptoms of burning food either too fast or too slow. That people had had exophthalmic goiter operations and were not well, and there was quite a big percentage of them, was due to the fact that they still had exophthalmic goiter in a mild form and one cut off only part of the disease when one cut off part of the thyroid. That was a point he knew to be true. Clinically it was true and also metabolically.

The "Adrenalin Hypersensitiveness Test" in the Diagnosis of Hyperthyroidism.—Dr. EMIL GOETSCH of Baltimore presented this paper, in which he stated that it was the purpose of the paper to report the results of a clinical study of approximately 300 cases of thyroid disease in the human subject with especial reference to the sensitiveness of these patients to hypodermic administration of adrenalin; to show that in clinical states of hyperthyroidism there was an increased tolerance for adrenalin hypodermically administered; and to indicate the practical application of this knowledge to the study, diagnosis, and treatment of thyroid disease in the human subject. With the abundant physiological evidence that increased thyroid secretion caused a hypersensitiveness of the sympathetic nervous system to the action of adrenalin, he thought it would be of interest to test the reaction of human patients suffering with hyperthyroidism to the subcutaneous administration of adrenalin. His thought was that if thyroid secretion sensitized the sympathetic endings to the action of adrenalin it was reasonable to suppose that a sudden increase of adrenalin in the circulating blood would call forth active responses throughout the domain of distribution of the sympathetic nervous system. This result he had found to be remarkably constant. The work was begun five years ago while he was in the surgical clinic of Professor Cushing and continued during the past four years in the clinic of Professor Halsted at Johns Hopkins Hospital. To his great surprise and satisfaction the first patient exhibiting hyperthyroidism, a case of exophthalmic goiter, gave a sharp reaction to the injection of adrenalin, and since that time he had personally carried out or supervised the carrying out of the test in 300 cases of thyroid disease and in approximately 100 conditions simulating in many respects hyperthyroidism. In a so-called positive reaction there was usually an early rise in systolic and a fall in diastolic blood pressures. In a very mild reaction the fall in diastolic pressure might occur alone. There was a rise in pulse pressure of at least 10 and sometimes as much as 50 or more millimeters of mercury. In the course of 30 to 35 minutes there was a moderate fall of the pulse and blood pressure, then a characteristic secondary rise and a second fall to the normal in about one and a half hours. Together with these changes one saw an exaggeration of the clinical picture of Graves' disease or hyperthyroidism brought out, especially the nervous manifestations.

The Principles Underlying the Treatment of Toxic Goiters.—Dr. CHARLES H. FRAZIER of Philadelphia said that to interpret competently the nature of the thyroid disturbance and to deal effectively with it one should carry in his mind the physiological basis for the symptoms of the toxic goiter. In large measure the symptoms were traceable to disturbances of the involuntary nervous system, with its dual representation into the autonomic and sympathetic system; in the former the third, seventh, ninth, tenth, and eleventh cranial nerves and the visceropelvic nerves; in the latter the cervical, thoracic, and sympathetic nerves. Practically every organ, except the brain, was represented by this dual supply, the autonomic being stimulating in character and the sympathetic inhibitive to action. The discussion of treatment would be restricted chiefly to the selection of cases for operation and to the choice of operation. By this he did not mean to infer that the management of the toxic goiter belonged solely to the domain of the surgeon. The instances of favorable response to therapy other than surgical were too numerous to warrant such an assumption. He must confess with regard to agencies other than surgical that his experience with them has in many instances been disappointing, and this was particularly true of the *x*-ray and radium, with such drugs as the hydrobromate of quinin and ergot, and with the glandular extracts, more particularly extracts of the thyroid, the thymus, and the suprarenals. If he were to attempt a classification of all the patients

he had seen with toxic goiter from the standpoint of treatment they would fall into one of five groups: (1) The mildly toxic of the adolescent group. The enlargement of the gland was compensatory in nature, the toxic symptoms were not constant and when present were of mild degree. Proper supervision of the girl's life, as to hours of work and sleep, restriction of studies for the school girl, with a trial of iodine internally, would tide the patient over a period of thyroid disturbance from which, upon entering womanhood, she might be entirely free. (2) The mildly toxic of the adenoma group. If under proper supervision there was no tendency to progression, the question for or against operation would depend in large measure upon how much the patient was handicapped either in work or recreation. It was largely a personal equation and the decision might be left often to the patient in consultation with her physician. At all events operation was one of choice and not of necessity. As a subdivision of this group might be entered the patient of definite neurasthenic type with small adenoma. These were puzzling cases and he knew of no criterion, when the basal metabolism was not above normal, by which the surgeon was to determine whether the neurasthenia was dependent upon the thyroid disorder. The patient and her physician must be advised of the element of uncertainty and the chances of failure should operation be requested by both patient and physician, as it often was. (3) The grave toxicosis of the adenomata, not the true exophthalmic type, but its equivalent in so far as the gravity of the prognosis. If the condition was not already inoperable, as it sometimes was, no time should be lost in inaugurating a course of treatment leading up to an eventual resection. (4) The initial hyperplastic goiter, without the precedence of an adenoma, appeared most often in the early years of the third decade. In this group he took a very positive position as to the preponderant advantage of surgical attack. The prognosis without operation was grave, the operative risks in the early stages trivial, the period of convalescence short, and the end results so satisfactory. Contrast this with a later stage, when the disease was present in its more aggravated form, with all that implies, in degeneration of the heart muscle and cardiac dilation, in gross metabolic disturbance, in utter demoralization and loss of nervous stability, and the arguments in favor of operation in an early stage were self-evident. The risks of operation must now be reckoned with and the possibility of a complete recovery were in the late stage appreciably reduced. (5) The degenerative or atrophic or the terminal stage of a more or less prolonged hyperplasia. There came a time in certain cases when, should the patient survive the hyperplastic stage, definite signs of hypoplasia were apparent. Manifestly here there was no justification for the removal of gland tissue.

Dr. Harold L. Foss of Danville said that those who saw much thyroid work, saw cases in which there was toxemia which simulated the toxemia of acute Graves's disease, but in which the manifestations were those of a true adenomatous goiter. Dr. Plummer was clearing it for us very nicely and in the papers that he knew he was about to publish he was sure the whole subject would be elucidated. Dr. Goetsch's test was going to find its greatest value in the hands of the general practitioner, for this reason, that now every goiter that came to the surgeon had been treated with every sort of a drug and chemical that one could conceive of until in the vast majority of these cases, particularly in the exophthalmic forms, the degenerative changes in the heart and nervous system and kidneys were so advanced that these patients were a profound risk. It was due to the fact that the general practitioner had not had at his command a means by which an accurate diagnosis could be made. He was far away from the medical or surgical center, he had not the time, he believed the case was a toxic form, he waited for exophthalmos, which appeared only in a certain number of cases, and the case drifted along because of the lack of a definite diagnosis being made. He believed the Goetsch test would be of inestimable value in the hands of the surgeon, yet it would find its greatest value in the hands of the general practitioner. He would be able to submit his patients to this test, and a larger number of them would then be referred in time so that the surgeon could bring about a cure. If there was anything pernicious in medicine it was the haphazard treatment of these cases. He did not see a goiter case that had not had all sorts of glandular therapy and drug treatment applied for weeks, months, and years in some cases before he saw them. Dr. Kendall had examined gland products exploited by drug houses and found the vast majority to be inert and also found that the quantity of gland tissue as advertised in the various tablets varied very, very widely. He thought that unquestionably surgery was the treatment of goiter for all cases, except the diffuse goiters of young girls and the advanced exophthalmos; he meant adenomatous goiters with advanced degenerative changes in the heart, so that operation was out of the question. He believed we could cure more than 70 per cent. of our cases if sent to us early. That should be 90 per cent., it should be 95 per cent., and the responsibility for bringing this about rested upon the men who were called upon to make the primary diagnosis.

Dr. George P. Müller of Philadelphia said that Dr. Plummer's papers had been of inestimable value, particularly in understanding the borderland and unusual type of cases. He had made two statements in his remarks that he thought instructive. One was the fact that the toxic adenomata were so successfully cured. He supposed he meant by operation. The other was in regard to the necessity of differentiating between the adenoma and a diffuse hypertrophy. When one had a toxic adenoma he could tell the relatives he was almost certain to cure that case by operation. When there was diffuse hypertrophy, if of moderate or severe grade, one must be cautious as to the prognosis because in the first place there was a large percentage of recurrence and a certain percentage of failures and mortality. As Dr. Frazier said, the decision for operation must go hand in hand with the personal equation of the patient. He would venture the remark that in spite of the weight of usage he had gotten away almost entirely from preliminary ligation. He believed that anatomically the ligation of the superior artery did not diminish the blood supply appreciably. One could accomplish the same result from the anociassociation standpoint and also probably from the anatomical standpoint with properly directed hypodermics of boiling water, and one did not have the searring and other interference that had to be done with lobectomy. One would never have trouble with the parathyroid if one did the resection operation in place of a lobectomy, and, furthermore, it was just as easy to do a double resection in a moderately severe case at the time of operation as to do a single one. The time spent at the operation was in the opening up, and so if one were pressed for time one could save time by leaving them open, closing normal muscles and skin, etc., at a little later date.

Dr. Thomas G. Simonton of Pittsburgh said that a number of years ago he had stumbled across a case which was referred to him for treatment, a case of exophthalmic goiter, marked exophthalmos, tachycardia of 150, loss of 50 pounds in two weeks; cutaneous eruption around the joints. The Wassermann showed 4 plus. The young man entered the hospital, having agreed to remain at least three months. The day after he was admitted he received 0.4 of a gram of salvarsan and at the end of the week he had received a second dose. At the end of that time there was marked decrease in pulse rate, it had come down to 100. The gland had decreased in size. He began to sleep, and in four weeks the gland decreased until it was barely palpable. His pulse rate had fallen to 80. He had gained 15 pounds in weight, slept well at night, and at the end of six weeks was allowed up in the hospital. When he left he had a negative Wassermann. He had since been working and had regained his weight and the gland was barely palpable. It seemed to him it was well to have the Wassermann test, and in case it was positive to try specific treatment to see what effect it would have.

Dr. Albert F. Hardt of Williamsport said that Dr. Goetsch's description of his adrenalin test was certainly most interesting and instructive and was new to most of his hearers. It certainly deserved a thorough trial as an aid to diagnosis. A point brought out by Dr. Frazier and Dr. Foss was the utter uselessness

of certain treatments described by many physicians. The indiscriminate use of iodine and various glandular preparations, and especially the use of electricity. Now many times we had patients come to us with a history of having been treated by Dr. So-and-So with electricity, saying their thyroid had been reduced two inches. We all know that the size of the thyroid had nothing to do with its toxicity. The small thyroids, scarcely palpable, might be intensely toxic.

Dr. ADELAIDE ELLSWORTH of Warren said that she wished to speak of the value of Dr. Goetsch's test. She had used it routinely for a number of months in differentiating the nervous and circulatory disturbances that arise in cases of neurasthenia, hysteria, and the psychoneuroses from subacute hyperthyroidism. So many times the symptoms in those subacute states were so mild that you felt that you had suggested them to the patient rather than that the patient had made the suggestion, but an application of this test left no doubt. The symptoms would vary, of course, with the amount of toxicity present. She did not bear Dr. Goetsch any ill-will, but she felt that his reprint should be in the hands of every practising physician to enable him to differentiate these borderline cases from true cases of hyperthyroidism. So many women were called neurasthenics when they were not neurasthenics, they were cases of mild hyperthyroidism.

Dr. EMIL GOETSCH of Baltimore said that he had never yet seen a case that had had a bad postoperative course if it had had a mild reaction before operation. But in those cases which had had a sharp reaction before operation there had generally been a stormy postoperative course. So, forewarned, one got operation through in a hurry, whereas otherwise one was apt to delay a little bit and it might mean those 15 minutes which would give a bad result. He had not seen a test yet that was infallible, but if it was 95 per cent. good it was valuable. In regard to the case in which syphilis was found, he had had a precisely similar case and he did not want to discourage the point of view that there might have been a connection between intoxication of syphilis and hyperthyroidism. The patient had received antisyphilitic treatment for a long time. The Wassermann was negative. The exophthalmic goiter did not improve. She required four operations before she was anywhere near in shape for her work. On the other hand, he thought there must be an association between definite syphilis and an expression of hyperthyroidism.

Surgical Treatment of Carcinoma of the Stomach.—Dr. HARVEY F. SMITH of Harrisburg read this paper, in which he stated that very definite progress had been made in the diagnosis and treatment of cancer of the stomach during the past several years. Advances in diagnosis had come through the *x*-ray and through the pathological study of fresh surgical specimens. The former in the hands of an expert had reached the point of 90 per cent. accuracy, while the latter had given a better appreciation of underlying conditions and a clearer interpretation of the sequence of events in cases of recurrent, painful, periodic gastric disturbance. Progress had been made in the treatment by incorporating additional points in technic, which not only had eliminated many previously existing difficulties, but had permitted more thorough, frequent and extensive resections. Gastric surgery had thus been placed upon a firmer basis with a larger recognition of the operability of cases which a few years ago had been considered inoperative. The improved methods of diagnosis were of vital interest to the surgeon, for, after all, the real value of surgery in the treatment of cancer of the stomach depended upon operation while it was yet a local condition. Approximately 70 per cent. of stomach cancers were located at the pyloric end. This group furnished the largest number of resectable cases. Further progress in the surgical treatment of cancer of the stomach must depend upon very positive and active co-operation of the family physician, *x*-ray expert, and surgeon. The physician had the difficult and vitally responsible task of promptly deciding what patients with gastric malfunction were medical and what were surgical. The roentgenologist should be given the opportunity for the "once over" in every individual approaching the so-called cancer age who had an unexplainable anemia, with or without gastric symptoms, or who had digestive disturbances which became progressively worse in spite of diet and medical care. The surgeon should be called more frequently to consult in a doubtful diagnosis than to confirm a positive one.

Dr. J. STEWART RODMAN of Philadelphia said that he thought this was a very important subject and that Dr. Smith had presented it in a very attractive form. Nineteen years ago his father first pointed out in his Oration on Surgery before the American Medical Association the principle of excising ulcers of the stomach — the ulcer-bearing area usually at the pylorus, but elsewhere if the ulcer was situated elsewhere. He did this because of the possible danger of subsequent perforation and hemorrhage and first and most important of all malignant degeneration. As Dr. Smith had said, there was a definite clinical and pathological evidence that gastric ulcers did become malignant. If that was the case, the important thing to do was to get rid of the ulcer if we could. He did not think that we could always do it. In that case gastroenterotomy was the operation of choice. Increasing experience had shown that wherever possible gastroenterotomy alone was not the ideal operation for ulcer of the stomach and that it should be supplemented by pylorectomy and excision of the ulcers of the lesser curvature.

DR ALFRED C. WOOD of Philadelphia said it had seemed to him on occasions that if all that we had been taught of the symptoms of carcinoma could be forgotten and if we could start entirely fresh we would really make a little progress. For instance, he did not think we had gotten away from the teaching he had heard 30 years ago that in cancer, wherever found, we might expect pain and loss of strength and weight, anemia, cachexia, enlarged glands, a mass, and so on. Now we all knew that these were the symptoms in the advanced stages of the disease when operation could be only palliative, if anything could be done at all. So that it seemed to him that we ought to stop talking of these things. They were of no help in the diagnosis at the time when operation might be curative. As had been pointed out and as we all knew, of course, the *x*-ray was of the greatest assistance in making a diagnosis at the earliest stage in gastric meal function. There was no other aid that was of such early and definite benefit as the *x*-ray in skilful hands. He presumed that that meant a very intensive and extensive study. One or two plates taken of the stomach without any opaque substance having been introduced were of no avail, and yet patients were brought by their physicians with an *x*-ray plate, sometimes two plates, for diagnosis as to whether they had cancer. An *x*-ray study by a competent man would give us the earliest information that we could obtain to-day, not of cancer, but of some lesion, and he was one of those who were willing to accept the evidence of the Mayo Clinic that cancer was a late stage of ulcer in a great many cases. So that we did not want to wait until we had cancer of the stomach; in order to give the patient any benefit we wanted to operate on his ulcer. Now, if we had a case of continued indigestion, with a train of symptoms that were suggestive of ulcer, and the *x*-ray failed us, or we couldn't get an *x*-ray, and, if we had had all the medical talent that was available in that location, without reaching any definite conclusion he must admit that he was in favor of doing an abdominal exploration to settle the point. So far as the curability of cancer of the stomach was concerned, of course, it was a surgical condition; there was no method of treatment by drugs, but there were well authenticated cases of cure from resection.

Dr. M. BEHREND of Philadelphia said that he had been struck recently by the great number of cancers in young people around 30 years of age. Only recently he had had to operate on a man 30 years old who had a carcinoma of the pylorus, with a metastatic growth of the liver.

D. J. J. GILBRIDE of Philadelphia said that we had a group of cases in which the onset was sudden. In this class of cases we were better prepared to meet the condition than we were in those which had existed for a long time. Personally, he did not feel that the general practitioner was to blame for the late diagnosis in chronic cases. The patients did not visit the physician. Their symptoms were not sufficiently severe to

warrant their going to a physician. Men of fairly robust health did not notice anything particularly wrong with them until perhaps they had passed on to a rather advanced stage.

JOINT MEETING OF THE SECTIONS ON MEDICINE AND SURGERY.

Third Day—Thursday, September 25.

Symposium on Diseases of the Gastrointestinal Tract: Diagnosis of Cholecystitis and Gallstone.—Dr. DAVID RIESMAN of Philadelphia read this paper, saying that no time needed to be taken up with a discussion of gallstone disease when it presented the classical symptoms. If it always produced such symptoms the subject would lose much of its perplexity, but at the same time much of its interest. There were few conditions in the body that created such confusing pictures as disease of the gallbladder. Since it was admittedly difficult to distinguish between gallbladder disease with and without stones, he would treat them as one. Gallstone disease appeared in two principal forms, (a) in the form of recurrent attacks with intervals of fairly good health, and (b) in the form of ill-defined gastrointestinal symptoms that might point to gallstone, gastric ulcer, duodenal ulcer, appendicitis, or other conditions. The pain of the gallstone attack was probably most often located in the epigastrium; next most frequently in the liver region, either below or above the right costal border, but it might be in the lower part of the abdomen near the appendix, in the neighborhood of the umbilicus, or even in the left hypochondrium. The pain was usually associated with tenderness which, however, was as a rule more circumscribed in distribution than the pain. Sometimes the tender spot was no bigger than the tip of the finger. At others it was a moderately large rounded area. As a normal gallbladder could never be felt, a palpable gallbladder was *ipso facto* proof of the disease. There were several points of value that such a history might bring out: (1) the attacks of gallstone colic were frequently nocturnal, wakening the patient from a sound sleep; (2) they came on with little or no warning; (3) between attacks the patient was often quite well, had a clean tongue and a good appetite, though often troubled with gas; (4) attacks were sometimes months or even years apart, but might occur at frequent intervals; (5) a history of acute indigestion or of ptomaine poisoning should arouse suspicion. Acute indigestion, so often given as the cause of death or as the cause of very sharp abdominal pain, was generally a misnomer; if it came on without warning in an adult in middle life, it was usually either angina pectoris or biliary colic. (6) One should always ask the patient whether the pain had been severe enough to require morphine injection. An affirmative answer was a point in favor of gallstone. (7) The presence of gallstones in the feces was not common, but he thought that if we had our patients look for stones systematically after all sudden attacks of pain in the upper abdomen, they would be found more frequently. The gastric crises of locomotor ataxia were most important, the underlying spinal disorder being overlooked. Chronic pancreatitis, the result of gallbladder infection, whether it be primarily lymphangitis, as was held by Deaver, or due to extension along the duct, was not easily distinguished from gallstone disease, and since the treatment was the same, pre-operative differentiation was not so important. The differential diagnosis between gallstone disease and appendicitis was sometimes impossible. Renal calculus, unilateral hematogenous nephritis, spondylitis, and lead colic were possible sources of diagnostic error in relation to gallstone disease, just as they were in relation to disease of the appendix.

Dr. J. J. GILBRIDE of Philadelphia said he felt that there was no part of the body that was more neglected than that involved in disease of the gallbladder. Therefore, in these cases one should not wait to find all the symptoms, for in such cases the disease dates back many years. In chronic disease the common symptoms were indigestion, distress, and periodical pain. It might be once in six months, once a year. A stone in the gallbladder might not produce any symptoms whatever, except indigestion and pain. If there was an infection, there would be jaundice. In stone in the common duct there was practically always jaundice. Sometimes there was nothing but a history of pain. In the absence of jaundice he thought a clear history of pain was the most valuable symptom. It might be referred to the right shoulder, to the left shoulder, or to the left side. Occasionally the pain might be referred to the umbilical region. He had seen cases of gallstone where pressure over the gallbladder did not produce any tenderness whatever.

The Value of the Roentgenologic Study of the Gastrointestinal Tract.—Dr. HENRY K. PANCOAST of Philadelphia read this paper, in which he stated that within the past few years very little had been added to the latitude of diagnosis by this means. It was well for the internist or surgeon to realize the exact dependence that could be placed upon a roentgenological study in any given condition, and especially upon the work of the roentgenologist in their locality to whom they referred work of this kind. Misplaced confidence would reflect upon them and lack of deserved confidence would deprive them of valuable assistance. The roentgen examination of the gastro-intestinal tract was in no way to be regarded as a substitute for a careful and thorough clinical study of a case. It had a well recognized and established place as a method of examination to assist in reaching correct conclusions, just as had the clinical study, and it had well defined limitations with which everyone should be thoroughly conversant. An examination of the gastrointestinal tract was in a large measure, aside from the observation of filling defects, a physiological study by an unusual means of watching the mechanism of the progress of an opaque meal for the purpose of detecting interference with normal physiological action. It, thereore, required time and patience on the part of both patient and examiner. A complete study could not be accomplished in less than three days, and frequently required more. It was fully time that the fact be recognized that the making of three or four roentgenograms without a proper roentgenoscopic study was not the correct or accurate way of making a gastrointestinal study, and yet cases continued to come with a positive diagnosis of serious lesions based upon no more evidence than very doubtful filling defects shown on one or two plates without any fluoroscopic study. Or, on the other hand, serious lesions had remained undetected because of a lack of adequate study through undeveloped technic. Such examinations were usually a waste of time and also a poor investment, and the conclusion, being without foundation, might be misleading and even dangerous. There was a widespread manifestation of lack of skill and experience in gastrointestinal study. More men were specializing in roentgenology now than ever before. It was partly the duty of internists and surgeons to see that not only those men kept abreast of the times, but also those who had been doing this work for some time. The new men had usually completed a thorough course of training, but he must continue to read, study, attend meetings, and visit others and see their work, because advances in roentgenology were so rapid that one soon fell behind, and the hermit roentgenologist rapidly became a useless member. Roentgenology was not a field for fanciful diagnosis unless one was very certain of his premises. The internist or surgeon wanted reliable facts. Opinions must be grouped as positive, negative, or those coming under the head of suspicious. A roentgenologic study of the gastrointestinal tract might be regarded as fulfilling one of three purposes: First, it might verify a clinical diagnosis either by substantiating or disproving the presence of a serious condition as, for example, ulcer or carcinoma, in both of which it could now be depended upon. Second, it might assist in deriving a correct diagnosis by supplying information that could not be determined in any other way or might be uncertain clinically, as in the same conditions with an uncertain clinical picture. Third, indefinite cases in which a clinical diagnosis could be not be centered upon any particular condition. In such instances the roentgen study became more difficult and complicated and might have to include a study of the gallbladder and urinary tract, and possibly other parts as well.

Dr. JOHN H. GIBBON of Philadelphia said that the

advancement in the diagnosis of gastrointestinal lesions had been very much due to what the roentgenologists had done. Dr. Pancoast, however, had given a word of warning and probably he could emphasize it more than any roentgenologist would like to, that is, the danger of operating on the interpretation of an inexperienced roentgenologist or upon the apparent lesion shown in plates. May of us had come a cropper when we had followed and rested entirely upon such a diagnosis.

Thorough Study vs. Exploratory Incision in Gastrointestinal Lesions.—Dr. JOHN H. GIBBON of Philadelphia read this paper, in which he said that it was admitted that the so-called exploratory incision was a justifiable surgical procedure under certain circumstances. There should, however, be an honest effort on the part of internists and surgeons to reduce and limit these circumstances. It was very easy to fall into the habit "of exploring," or "opening to see," but it required some effort to develop the habit of studying our patients carefully, of weighing symptoms, and giving them their relative value, and of taking into consideration the contraindications as well as the indications for operation. This easily acquired habit rendered one a poor internist or surgeon, with little likelihood of further development, while the other made him a man whose opinion carried weight and who was apt to progress in knowledge with experience. A common excuse for neglect of proper study and resort to immediate exploratory incision was the supposed urgency of the patient's condition and the saving of time. While this excuse might be legitimate in one case, it was not applicable in nine out of ten so-called emergencies. His own experience led him to believe that errors in diagnosis and the mistake of doing an unnecessary operation were not due to ignorance, but to carelessless, to what might be called "cock-sureness." One of the great disadvantages of an incorrect abdominal diagnosis was the fact that in order to reach satisfactorily the real lesion, another abdominal incision might be necessary. Another point which was worthy of consideration in this connection was the importance of examining our patients before operation for conditions quite different from those which caused the patient to present himself to us. The time to discover a lung lesion, a Bright's disease, a hyperthryroidism, a venereal disease, or a kidney infection, was before, not after, operation, and such a discovery might be the means of saving to the patient his life and to the surgeon his reputation.

Surgical Treatment of Lesions of the Gastrointestinal Tract.—Dr. ALFRED C. WOOD of Phiadelphia read this paper, in which he said that the perforated ulcer was always a surgical condition. Medical treatment was not to be thought of for a moment. While this was not disputed in theory, in actual practice we still found an inexcusable delay in some cases. In most instances this must be charged to the physician, as it was very seldom indeed that medical aid was not promptly called. The urgency of the symptoms forced the patient to demand immediate relief. This being the fact, it remained only for the physician to make the diagnosis and start the patient on the way to the hospital. The symptoms and signs of acute perforation were usually so typical that there should rarely be any uncertainty, and, if such did exist in the physician's mind, the only safe course was to call a surgeon at once. Each hour of delay lessened the chance of recovery. On the other hand, chronic ulcers, including those accompanied by hemorrhage, belonged to the physician, at least for a time. That ulcers healed and remain healed in many instances was freely admitted; but that others did not heal, or tended to periodical exacerbations was also well known. He was not prepared to lay down any hard or fast rule as to just when the latter class should be turned over to the surgeon; but it seemed at least reasonable to say that after medical measures had been given a fair trial without permanent relief, it would be proper to have the surgeon join the physician in the case. After operation for ulcer he believed the patient should be returned to the internist for a prolonged course of observation, and such dieting and other treatment as might be necessary to promote rapid and complete healing of the ulcer, as well as to restore the normal gastric functions. Carcinoma of the stomach was still an unsolved problem. We had as yet no way of detecting the disease in its early stages, when a radical operation might be followed by a permanent cure. The result was that most of these cases came to the surgeon when only a palliative operation can be done, and in many instances even this was not possible. He did not wish to be considered as advocating abdominal operations until all approved methods of diagnosis had been exhausted; but it must be apparent to everyone that if a larger measure of benefit was to be offered these patients, operation must be done much earlier in the future than it had been in the past. It will not be disputed that every case of carcinoma of the gastrointestinal tract was a surgical problem from the beginning. It was not a medical condition at any stage, and yet almost every one of these cases had been under medical observation and treatment for a more or less prolonged period if not throughout its whole course. He desired especially at this time to stress the importance of diseases of the pancreas and of their close association with inflammation of the bile system. The evidence now at hand seemed to warrant the statement, first, that pancreatitis was frequently, if not in most instances, the result of infections of the bile tract; second, the only means known at present to prevent pancreatitis was to deal promptly and radically with cholecystitis and cholangitis; and third, when pancreatitis was present the most important factor in its treatment was efficient biliary drainage.

Dr. HAROLD L. FOSS of Danville said that errors in diagnosis were due to carelessness rather than the lack of knowledge as to how the diagnosis should be made. A number of years ago he had investigated the errors in the diagnosis of abdominal conditions in one of the largest clinics in this country and found that the gross errors as proven at the operating table were about 10 per cent. That was in a clinic where every possible means had been exercised in determining the correct diagnosis before the patient was sent to the hospital. There were experts in every particular branch so the patient receives the benefit of these examinations and yet in that great clinic they were making about 10 per cent. gross errors in abdominal diseases; 65 per cent. had to do with duodenum, gallbladder, and appendix. He had found that the cases of errors in a large series of abdominal cases had had to do with gastric and duodenal ulcer. Gastric ulcers had been diagnosed as duodenal and duodenal ulcers had been diagnosed as gastric ulcers. In regard to carcinoma of the stomach, the whole thing rested with the diagnosis. With early diagnosis something could be accomplished. Unquestionably a large percentage of cases could be cured if seen in time. The Mayos had a large series living six and seven years who had had resections and the Polya operation performed and patients who had carcinoma, as proven pathologically, but the diagnosis must be made early and the diagnosis in these cases would rest chiefly with the clinical work and with the roentgenologist. Roentgenology did not help us in any part of the body to such an extent as it did in early carcinoma of the pylorus.

Dr. LAWRENCE LITCHFIELD of Pittsburgh said that he had observed a case in which root pains from a growing tumor pressing on the spinal cord had caused several abdominal operations. How many surgeons tested the patient who was suffering from acute or chronic abdominal pains for ankle clonus or disturbance of sensations in the lower extremities? How many surgeons had operated on the abdomen in the presence of ankle clonus? Another question for the internist: Cases came with glycosuria, they were diagnosed as diabetes, and treatment was begun when a careful search into the history might give vague symptoms of gallbladder disease which might lead to the diagnosis of pancreatitis and drainage of the gallbladder might clear up the glycosuria and the case might not have been a true diabetes at all. Just one for the surgeon: Many cases of perforative peritonitis did not present the traditional picture as to gravity. The history might strongly suggest perforation, but the physical examination did not seem to quite warrant opening of the abdomen. He had seen two deaths where surgeons had refused to open the abdomen because the patient had not seemed sick enough. A case with marked cachexia and easily palpated mass in the

abdomen was tubercular peritonitis, and that man had been running a large wholesale dry goods business for the last ten years following operation. In cases of suspected malignancy abdominal section would do no harm and might be an eye opener as well as an abdomen opener.

Dr. JOHN A. LICHTY of Pittsburgh said that he thought Dr. Pancoast had struck the keynote in *x*-ray work, that was it had to be coordinated with conditions in general, and he would like to add that the *x*-ray man who interprets his own plates, or rather who establishes diagnosis, would have to be a pathologist, or at least he would have to go to an autopsy quite frequently and he would have to be a clinician. He did not see how else we could allow the diagnosis to go over entirely to the *x*-ray men. He thought our good *x*-ray men were doing that. They were saying that pathology and clinical medicine was but a part of their sphere. If exploratory laparotomy was done it should be real. That was if the diagnosis was in question, however sure you might be about one organ or the other as being at fault, every part of the peritoneal cavity should be examined. He did not believe an operation for gallbladder trouble, cholecystitis as we call it, should be done without a previous Wassermann, and this should be done with the idea of determining whether syphilis was or was not present. Just in the last few weeks a colleague of his had opened the abdomen for chronic appendicitis and found a gumma on the ileum.

Dr. THOMAS MCCRAE of Philadelphia said that a mistake in operation was often made on account of careless examination. It was often contributed to by bad palpation. The physician often started in with what he called the finger-poking method, and palpated the abdomen with the tips of the fingers, sticking down here and there. If a man had superficial tenderness he elicited a great deal of tenderness and muscle spasm, would continue for perhaps an hour or two, and your colleagues who examined him later would find marked tenderness and muscle spasm. He believed the first point in abdominal palpation was to use the flat of the hand and palpate gently. A disease responsible for a certain number of wrong diagnoses was prostatitis. A good many abdomens had been opened for this with referred pains. He thought a great many of the statistics as to cases of gastric ulcer cured by operation were based on observations that did not extend sufficiently long. As regards carcinoma of the stomach, we had one of the most gloomy outlooks. He had seen in his wards a great many cases of carcinoma of the stomach in which operation was out of the question, except to relieve pyloric stenosis, and frankly he felt very doubtful of making a tremendous advance because we did not get the patient early enough. A campaign of education might help in ten, fifteen, or twenty years.

Dr. ALFRED C. WOOD of Philadelphia said that he had one clear recollection of a carcinoma studied in the medical ward because the signs were obscure. The physician said "He has symptoms that might point to ulcer or carcinoma; his hemoglobin is 60 per cent., his red cells are 3,000,000; he is a little sallow, but we will treat him for ulcer, and, if he improves, we will know that he has ulcer." He was treated *secundum artem* and improved, the red cells went up to four and a half millions. He gained in weight and the diagnosis was ulcer and he was sent home. In a short time he came back to the hospital. He was much worse. He was then subjected to operation, when an inoperable carcinoma of the stomach was present. He wanted to say finally that a patient with carcinoma could be built up in regard to blood, weight and so on.

Medical Treatment of Diseases of the Gastrointestinal Tract.—Dr. JOHN A. LICHTY of Pittsburgh read this paper in which he said that the points of difference between medical and surgical treatment of diseases of the gastrointestinal tract centered usually about diseases of the appendix, of the gall bladder, of the stomach, especially ulcerations, and of the pancreas. About the appendix there was very little difference of opinion. An acute appendicitis was plainly a surgical condition; a chronic appendicitis which was always difficult to diagnose, was not receiving the same enthusiasm from the surgical side as it had formerly, and was receiving more serious attention on the part of the medical man. With reference to peptic ulcer, there were still those who felt that it was a surgical condition, and only that. Evidently the difference of opinion here was largely due to the fact that the surgeon spoke of a different condition, a chronic, indurated, incurable peptic ulcer, whereas the physician spoke of an acute ulcer which might heal spontaneously, if left alone, or in which the healing might be brought about more promptly by care to diet and by the use of certain well known remedies and procedures. In diseases of the gall bladder matters were reversed, or rather the opposite of that of disease of the appendix. The acute condition received medical attention, the chronic condition was in nearly all cases the surgical condition. In disease of the pancreas, conditions were very much as in the appendix. The acute condition demanded prompt surgical procedure, the chronic condition most deliberate study and possibly largely medical and dietetic treatment. Through the studies in biological and physiological chemistry in coming years the field for medical treatment might be greatly enlarged This, however, would depend largely upon more exact methods of making an early diagnosis.

The Attitude of the General Practitioner.—Dr. WILLIAM EGBERT ROBERTSON of Philadelphia read this paper in which he said that the conviction was soon borne in upon the general practising physician, that in this field, as in most others for that matter, it was to him that the ailing individual first comes for advice, and that it was his privilege and duty so to study the patient's condition that relief might follow upon an exact diagnosis, or, that the thorough preliminary study might result in the selection of other counsel, most suited to the particular need of the case. Not seldom, a prominent pretuberculous phenomenon was digestive disturbance, with or without epigastric pain. When to this was added the loss of blood by mouth, the similarity to gastric ulcer was strong enough to cause a certain proportion of these subjects to seek relief by way of the operating table. If one accepts the view that general anesthesia by inhalation may awaken a latent tuberculous focus, or excite into greater activity one already active, the pathos of the situation becomes more apparent, and should increase the sense of moral obligation of the family doctor to whom such individuals first turned for relief. It was necessary, not alone to permit the patient to narrate his complaints, but to take a history and make a complete physical examination in every instance. Thus did we command the greater respect of the patient, and refuse to permit him to make his own diagnosis. The tendency on the part of the busy family doctor to accept a patient's diagnosis is somewhat frequent. That it led to errors of subsequent judgment, and in consequence, to errors in handling the patient, and might lead to operation unnecessarily, and because of this fact, may jeopardize or even sacrifice the life of an individual or may postpone till too late an operation that might have promised cure, these were the reasons which made imperative the more careful study of any patient who presents apparent gastrointestinal symptoms. How often was the doctor the advance agent of some drug concern? Thoughtlessly handing out a sample, he might invite the development of a habit of self-medication, or might aid in confirming a tendency already in existence. If notes were not kept and no record of the progress of the patient's condition was made, he was not able to recall the details either of the patient's condition or the treatment, hence he was forced to rely upon the patient's statements for these, as he had been for the diagnosis, and the patient was not slow to grasp the situation. The question of diet in the management of disease was rarely considered in a truly scientific manner. Even in the special field of gastrointestinal disorders we paid too much attention to drugs and too little to foods. The family doctor was given the opportunity to study the life history of the disease, and, if he did so carefully he would almost always be able to find that the victim was one who was fussy in his attitude toward his food, often failing to eat any breakfast, an inadequate lunch, and worn out and irritable, often in no condition to digest a meal, he would grumble over his supper, which might represent the only adequate meal of the day.

The Value of the High Rectal Enema.—Dr. HENRY D.

Jump of Philadelphia read this paper in which he said that Naunyn in 1896, Nothnagel in 1898, Boas in 1903 maintained that the flexible rectal tube always coiled in the ampulla of the rectum. Many of us had had the same experience in washing out the bowel of infants with a large catheter; for frequently the coiling of the catheter had permitted the end of it to reappear at the anus. Their work had been done at the Misericordia Hospital with the aid of one of the best trained nurses and a well trained orderly. Dr. C. P. O'Boyle of Dr. Pfahler's service had made the radiographs and to these gentlemen he was indebted for valuable suggestions. They had made persistent efforts with men and women patients in various postures, to run the tube into the sigmoid flexure. While this might be done under certain conditions it was difficult, uncertain, and in most instances impossible.

Dr. Robert A. Kelly of Danville said that some enemata are given for mere cleansing, some for catharsis, some for nutrition, and some for *x*-ray purposes. They had tried on several occasions at an autopsy to pass a tube high and had found that under exceptional circumstances only would the tube pass the sigmoid flexure at the brim of the pelvis.

Dr. Thomas McCrae of Philadelphia said that he thought Dr. Jump's paper was an extremely important one to take to heart, but he must say he had very little expectation that papers such as this would carry very much influence. The idea was so firmly fixed that there was a difference between giving fluid low down and supposedly high up that it was going to take a great many years and a great many papers before that idea would get into the minds of more than comparatively few. It was important for nurses in training schools to know this. A tremendous amount of time was lost in teaching nurses how to give this and that sort of enema. Practically it was time wasted. It was going to take a great deal of preaching before the idea got into the minds of the laity.

Dr. J. J. Gilbride of Philadelphia said that as for Dr. Jump's paper, those facts had been well known for 20 years and personally he did not know that we missed a great deal by being unable to pass a tube high up. Of course this paper would serve a purpose in emphasizing to others the needlessness of trying to do something that can't be done.

Dr. David J. Hetrick of Harrisburg said that some time ago he had had a nurse discharged from a little patient because she persisted in using a catheter high up. She gave the child intense pain. She said it was her teaching.

Dr. Henry I. Pancoast of Philadelphia said that there was one danger in the attempt to give a high enema. When the tube was kinked considerable more force had to be used to get the fluid into the rectum. It must be given slowly; if given too fast, there was sure to be spasm of the descending colon which would prevent the fluid going very far. The ileocecal valve served its purpose well when taking care of fecal contents, but when it tried to stop enemata it had no power to do this and it opened almost invariably. The time to stop barium enemata was when we saw the ileocecal valve give way. One case was on record where a barium enema had been vomited. He believed that in one instance the tube had been introduced as far as the splenic flexure.

Dr. Alfred T. Livingston of Jamestown, N. Y., said that the only thing that had not been mentioned was the most important of all and that was the technique of the enema. There was a tendency to spasm if you introduced the fluid rapidly, which gave great pain and obstruction of the flow of fluid. He found that approaching a pint this spasm would occur. When approaching a pint he stopped the flow, waited a few seconds and then slowly began again. If it passed a pint and a half he was sure that the sigmoid had relaxed and then he was sure there was a free passage. As a rule he gave 4 to 6 pints or even as high as 9 pints.

Dr. A. E. Roussel of Philadelphia said that a certain case had been carefully studied two years ago because of duodenal ulcer. The patient had been advised to have an operation after a sufficient length of time had passed without improvement in his symptoms under medical treatment. This had been refused. About a week ago he was seized with subacute pains and a clinician of good standing was called in. The temperature and respiration at the time were normal; there were no symptoms of shock. The pulse rate was but slightly increased and there were pains in the neighborhood of the gall bladder. A tentative diagnosis of the passing of gallstones was made and before the practitioner in question could visit his patient the next day he received word that the individual was up and that the necessity of his call was not apparent. He was not called upon until a day later. Dr. Roussel was called in the same evening and there was undoubtedly a general peritonitis and with the knowledge of the work done two years before it was comparatively easy to diagnose the case as one of perforation of a duodenal ulcer.

Dr. Alfred C. Wood of Philadelphia said that it might be worth while to call attention of the members to the dangers of making an effort to pass the socalled high rectal tube, but in spite of that, as Dr. McCrae had said, certain individuals still insisted on trying. No doubt most were familiar with cases in which in an effort to pass the rectal tube up into the sigmoid the rectum had been perforated and he had known of instances of that kind in which not only had the rectum been perforated, but the nurse had gone on with the administration of the enema, all of which had been received into the peritoneal cavity. Therefore, it seemed to him that Dr. McCrae's hint should be taken to heart and all who had anything to do with the teaching of nurses should impress upon them that, not only was there no occasion to pass the tube more than 2 or at most 3 inches, but that if they had a rather rigid tube there was very positive danger in it. In regard to the quantity of fluid that might be administered, he had been at the operating table in a case of severe hemorrhage in which the efforts of the physicians to sustain the patient until the operation might be concluded had been so persistent and aggressive that the salt solution put into the patient's bowel finally ran out of the mouth while he was operating. In another case he knew of the enema came out of the mouth from the constant desire to overcome, as supposed, fecal impaction, which did not exist. They added quart after quart until the fluid began to appear in the vomit.

Dr. David Riesman of Philadelphia said that few of them taught nurses how to give enemas. That was left to the nurses themselves, and, if Dr. Jump depended on the members to spread this doctrine to the nurses, it would fail; so he would suggest that he send his paper, with or without the permission of the Society, to all the nursing journals in the country. Dr. Robertson touched upon a matter which was very important and ought to be spoken of with a good deal of emphasis. We asked our patients whether they ate fast or slowly, whether they drank tea or coffee and whether they smoked to excess. But that was not enough. We must ask our gastrointestinal patients, our tuberculous patients, diabetic patients just exactly what they ate and we would be surprised if we asked this question systematically what interesting facts were obtained. Some never drank any water, some never ate any fruit, some had idiosyncrasies to this or that and some ate too much, but he believed much gastrointestinal disease and perhaps the tendency to tuberculosis was based on faulty diet. He had used for years in his own hospital and private work a mixture containing sodium bromide together with alkalies, sometimes with belladonna, but he had gotten just as good results without belladonna. That combination was one of the best he knew of in hyperchlorhydria.

Sugar as a Necessity.—The attempt in France to ration sugar seems to have failed for it became impossible to allot to individuals the quantities prescribed. In this connection sugar is stated to be a necessity for the sick, the child and the aged. It has been alleged that only by cutting down on supplies to pastry cooks, confectioners, comfit makers and cordial makers will families be able to secure the necessary ration of one kilo per person per month.—*Bulletin général de thérapeutique.*

THE EMOTIONAL UNREST, ITS CAUSES AND TREATMENT.*

BY STEWART PATON, M.D.,

PRINCETON, N. J.

PRESIDENT EUGENICS RESEARCH ASSOCIATION; LECTURER NEUROBIOLOGY, PRINCETON UNIVERSITY.

THOUGHTFUL people throughout the world are awaiting with interest the outcome of the Congresses in session in Paris and Washington; the one having as its object the improvement of international, and the other of social relations. In order to avoid any of the tragic consequences of great disappointments we should try to be temperate in our expectations of the amount of good that will be accomplished either in Paris or Washington. Although scepticism in regard to the extent of the promised improvements in human relations is justified, the fact should be remembered that it was a common interest in the study of emotional unrest which is responsible for both these great gatherings.

Any great or permanent improvement in human relations must be based on an accurate knowledge of the laws governing human behavior, and so far man has refused persistently to consider that human nature should be "the chief study of man." Occasionally some prophet, like the historian Lecky, has raised his voice protesting that human predispositions and not human arguments should be made special objects of study in the attempt to improve human relations, but the voice has been that of one crying in the wilderness.

An inquiry into the nature of human predispositions is an interesting, important, and if it is to be successful, one of the largest tasks confronting mankind to-day. We should know, and know immediately, more about the predispositions inclining men toward peace, be able to recognize and correct tendencies breeding suspicion, hatred and belligerent impulses, make intelligent efforts to cultivate the temperamental qualities requisite for the growth of the spirit of cooperation and rational adjustment of all difficulties and remove any doubt now present in the minds of thoughtful people as to whether the form of civilization man has created has not overtaxed his brain to such an extent that, having reached the apogee of his career, he has begun the period of decline.

A great deal of the present emotional unrest in the world seems to be due to two causes: on the one side there has been an exaggeration of the previously existing and well recognized types of emotional instability, and on the other a definite psychosis* with certain specific symptoms and markedly epidemic tendencies, affecting persons possessing intellectual ability, has become a menace to civilization.

The effects of this disorder have already imperiled the permanence of many human institutions, have made the establishment of conditions essential to the restoration of peace increasingly difficult, and have jeopardized that rational control of behavior which man acquired only after ages of toil and painful experiences. The causes of the disease are exceedingly complex, many of its symptoms are variable, and treatment after the initial stage is rarely successful.

Even a cursory survey of the damage directly and indirectly caused by this disease shows that it has resulted in a greater loss of productive work, more grueling disappointments, heartrending misery and more needless sacrifice of life than can be attributed to actual warfare. As far as is known no epidemic of equal magnitude nor as insidious in its method of propagation has ever swept over the world. The various epidemic forms of emotional disorder that have appeared at different times in various countries have to a certain extent been limited in their spread by the difficulties attending the dissemination of information and the mutual exchange of ideas. In the advance of civilization the means have been supplied not only for the diffusion of useful knowledge, but also, and this should not be forgotten, the paths have multiplied permitting the rapid extension of the kind of information apt to cause in the emotionally unstable person a serious dissociation of the personality. The peculiar mental attitudes of the Middles Ages, as expressed in beliefs in witchcraft and demoniac possessions associated with delusions in regard to the future life filled with torments, "for centuries diseased the imagination and embittered the character of mankind." To-day in place of these disorders of fancy, which at least had an element of picturesqueness, we are confronted by a definite disturbance of temperament and character peculiarly insidious in its method of propagation and development.

A few of the characteristics which we have learned by experience to accept as indicating the presence of a sound mind in a sound body are enumerated on Chart I, and a comparison of these with the unsatisfactory adjustments of the

*Read at a meeting of the New York Academy of Medicine, Oct. 16, 1919.

*The word psychosis is used in this paper to describe a condition marked by discords of adjustment in the emotional and intellectual levels indicating that the expenditure of energy is not intelligently regulated.

psychoneurotic intellectual Chart II will assist us to understand the nature of the present epidemic psychosis.

I.

SIGNS OF SANITY.

A. *Subjective Signs*:
1. Joy in living.
2. Pleasure in work.
3. No desire "to varnish the fair face of truth with the pestilent cosmetic rhetoric"—Huxley.
4. Temperate in wishful-thinking.
5. No apologies for self-insufficiency.

B. *Objective Signs*:
1. Prompt action in emergencies.
2. Behavior controlled by normal, and not supernormal idealism.

The basis of "the joy in living" and "pleasure in work" experienced by every sane, healthy person is a sense of adequacy and self-sufficiency, which is one of man's greatest and least appreciated possessions. To understand the great complexity of these reactions we should remember that the muscular system, which is millions of years older than the nervous system, gives the "set" to all our activities, and to a very large extent determines our attitude in general toward the environment.

The extreme antiquity of the executive department creating fundamental motor dispositions emphasizes the imperative need of satisfying these tendencies by action if the balance of the personality is to be preserved. The motor set expressed in the general tonus and postural positions leads to what Woodworth describes as preparatory and consummatory reactions. The former prepare the organism to face and the latter to surmount difficult and critical situations. When this series of reactions runs off smoothly the immediate goal is achieved and a sense of satisfaction and self-sufficiency is the result. If, however, the preparatory reactions prepare the organism for situations that do not develop, or if they do but are too complicated for the consummatory adjustments to be effective, then defeat is registered in a depreciated sense of adequacy and lowered self-sufficiency. This condition may result from either the defective functioning of internal organs or limitations in the integrating capacity of the brain and nervous system, and if some satisfactory compensation is not quickly arranged, the seeds of serious trouble have been sown. What the nature of the trouble is has been outlined on the second chart upon which are recorded a few of the reactions responsible for the peculiar traits shaping the personality of the psychoneurotic intellectual.

II.

PERSONALITY OF THE PSYCHONEUROTIC INTELLECTUAL.

A. *Primary Reactions*:
1. Self-insufficiency.
2. Mental depression or unusual exhilaration.
3. Dodges critical situations.

B. *Compensatory Defense Reactions*:
1. Artificially reinforced ego.
2. Substitution of platitudes for concrete terms.
3. Transfer of interest to affairs of other people.
4. Prefers discussion of "class problems" to "personal problems."
5. Cultivates two distinct personalities, one for friends, the other for enemies.
6. Believes in selective class salvation.
7. Superidealism.

The gnawing sense of inadequacy, the compelling force in the life of the psychoneurotic, drives him often headlong to seek for some quick method of repairing his weakened personality. Having failed in the beginning to face a trying situation, reason cannot be relied upon to prepare the first line of defense. The primitive herd instinct urges the sufferer to find some kind of company, as any suggestion of being left alone or of being thrown back upon his or her own unaided resources is an irritating and often a tormenting idea. Instead of admitting frankly the real source of the drive springing from the failure to get square with life, it is ignored and temporary relief from personal inadequacy is found by reiterating such phrases as "internationalism," "social uplift" and others that are equally unsuggestive of the sting of personal defeat and bring some kind of assurance that misery not only loves but expects to find company. The kind of partisanship developed as a cloak to inadequacy is similar to that described by Galen as "harder to heal than any kind of itch."

The psychoneurotic, having failed both to discover and to comprehend the motivating forces in his personality and finding it exceedingly difficult to satisfy pressing needs, becomes very impatient with the slow progress of social events. Skilled in the art of self-deception and having failed to adjust himself to the old world in which we all live, he persuades himself that he is living in a new one and either has become or will become soon a citizen of some kind of new republic. A similar form of compensatory reaction appears in persons fatigued by prolonged physical or mental effort.

One more point in connection with the direction given to desire by the feeling of self-insufficiency needs to be emphasized. The effect of the embarrassing memory of unsolved personal problems is partially offset by calling up ideas suggesting class distinctions. The effort is made to forget personal unequalness to the task of trying to adjust life at an unattainable level by making frantic attempts to obtain equality for first this and then that social class.

Forced to abandon logic, the inadequate revels in the temporary stimulation supplied by thinking of "class distinctions," and during the process of self-hypnotization some comfort is found in the medieval doctrine of selective salvation. First it is the upper, then the lower, and now the middle class, and incidentally the one in which the inadequate has applied for membership, that is especially appointed to be saved.

The consequences of depriving reason of the executive control of behavior may easily be imagined. There are then, after the wandering of desire begins, no coordinating influences sufficient to shape a well rounded personality.

Baffled in the attempt to grapple with reality reason is side-tracked, while fancy is turned loose to weave romances to be used as programs for the daily life. In the struggle to meet the ordinary

needs of the hour, the disorganized personality dissipates much energy in trying to reconcile fact and fiction.

As a sequence to this conflict there is a definite tendency to "overlook the possible good for the sake of the impossible better." This tendency has not only disastrous effects in continuing the disorganization of the individual personality but, as a great historian has intimated, has been responsible for many of the tragedies in the history of mankind. Many minds are extraordinarily fertile in devising expedients for continuing the search for the impossible better, but a closer analysis makes it evident that the genuine constructive impulses depending upon the close cooperation of imagination with reason do not exist in this type of person. The defect is not merely a negative one, but is responsible for the liberation of a great variety of blind but destructive impulses. This is the price paid for the removal of the executive control of reason.

Today in all parts of the world there are countless examples of the disintegrating effect of good intentions upon minds already disorganized by the reduction or deficiency of a genuine, normal self-regarding instinct.

The balance beam in the personality is to a very large extent, as has been indicated, the normal feeling of sufficiency, and unless it is present the integration of various tendencies and interests is no longer effective, and reason cannot operate except at great disadvantage.

When reason becomes subservient to fancy the announcement of the purity and elevation of ideals is not, as many people seem to believe, convincing evidence of the existence of a sufficient number of sluice-ways to carry off the floods of emotion accumulated as the result of wishful-thinking. This form of unpreparedness is also increased by such American characteristics as unwillingness to think through, defective psychological insight, and by a very limited experience in practising the gentle art of living.

The disorganization is carried still further by the presence of superideals, which are really parasitic growths attached to the personality in order to conceal basic defects. The detachment of superideals from the main personality results frequently in their being treated like the best furniture, which is kept in the parlor and exposed to view only upon state occasions. When these unusually lofty aspirations are paraded, their sponsors become exceedingly nervous, first on account of the evident detachment and second because any suggestion that the epiphenomena are not genuine products of the personality is quickly resented.

Examples of conflicts referable to causes similar to those described occur in academic circles. The academic mind is sincerely convinced of the righteousness of the cause advocated, but by reason of the protecting influences removing the scholar from the rough and tumble struggle of the world, fancy often constructs a set of ideals which do not fit the personality. This defect is generally not suspected until the public notices the misfit, and then the intemperate idealist, exasperated by unfavorable criticism, gives *carte blanche* to fancy to suggest some escape from an embarrassing situation.

In many instances wishful-thinking indicates the line of retreat. The introduction of this form of compensatory reaction explains why academic discussions are often conducted in a manner that is, to say the least, unedifying, and is an excellent additional reason for the universities taking active steps to encourage and promote the study of the human personality.

The success of the treatment of the present epidemic of "the malady of the ideal" depends to a considerable extent upon organization and preparation. In the first place, the information now available relating to prevention as well as treatment should be placed before the public in a convincing manner. The advantages should be pointed out that result from practising a good mental hygiene, and among these are increased efficiency, more pleasure in living, and a predisposition favorable for cooperative effort. It is reasonable to suppose that the spread of the disease will be much less rapid as soon as the fact becomes generally known that such diversified forms of mental aberration as are represented by believers in Christian Science and thought transference, as well as in the radical doctrines of many socialists and soviets, are the articles of faith of fugitives from galling memories of self-insufficiency.

The time has come for physicians to take a very much more active part in establishing the conditions essential for sanity. The city of Newark has already established a Department of Mental Hygiene under the direction of Dr. C. C. Beling and it is to be hoped that not only other cities but also our universities will soon follow the example of Newark. Of far greater immediate importance even than the establishment of these departments is the development of centers for the training of physicians in the art of studying human behavior. This work is one of the chief functions of a Psychiatric Clinic.

In 1905, the writer had occasion to use the following words: "Fortunate would be the community in which there was a fully equipped and well organized psychiatric clinic under the control of a university. . . . The mere presence of such an institution would indicate that people were as much interested in endeavoring to increase the public sanity as they are in the results of explorations in the uttermost parts of the earth or in the discovery of a new star." Conditions to-day in a tragic manner emphasize the need for an institution of this character in New York.

If we apply the rules of mental hygiene, paying less attention to arguments and more to the analysis of predispositions, it should be possible to develop the spirit of cooperation to the point of seizing the present opportunity, unique in the history of civilization, of creating in this city under university control a great medical school including a well organized and thoroughly equipped psychiatric clinic.

Our degree of sanity doubtless will be estimated by future historians by the amount of intelligent interest exhibited in solving the problems of human behavior.

OBSTETRIC PARALYSIS (ERB'S PALSY).

WITH A REPORT OF SEVENTEEN CASES.

By SAMUEL W. BOORSTEIN, M.D.

NEW YORK

INSTRUCTOR IN ORTHOPEDIC SURGERY, FORDHAM UNIVERSITY MEDICAL SCHOOL; ADJUNCT VISITING ORTHOPEDIC SURGEON, MONTEFIORE HOME AND HOSPITAL; CHIEF OF ORTHOPEDIC DEPARTMENT, FORDHAM HOSPITAL, O.P.D.; ADJUNCT ASSISTANT VISITING SURGEON, FORDHAM HOSPITAL, NEW YORK.

CASES of obstetric paralysis very often come under the care of the general practitioner and unfortunately he is frequently the first one to notice the paralysis after the tedious work of a prolonged delivery or a difficult forceps. The practitioner still remembers the old teaching that the deformity is due to injury of the plexus. Both he and the obstetrician usually regard these cases as quickly curable while the neurologist and the orthopedic surgeon probably regard them too seriously. It will therefore be of great interest to general practitioners to hear of the recent studies in this field and the latest methods of treatment. I will emphasize particularly the early orthopedic treatments which have till recently been entirely neglected. It is due mainly to the propaganda work of Sever that the orthopedic surgeon is now being consulted sooner than was customary and thus he has a chance to prevent the bad and distressing deformities which are usually the after effects of this mishap. Up till now the orthopedic surgeon was consulted only at a late stage when the deformities were present, as the general practitioner used to administer massage and electricity for the first two or three years. It is an established fact, however, that in all forms of flaccid paralysis a great deal can be accomplished by orthopedic methods, if treatments are begun early and contractures guarded against. I hope, therefore, that this demonstration will serve to stimulate you to early orthopedic treatments and not to allow any delay with the usual statement that they will get well of themselves, or that nothing can be done, or to be treated by the universal panacea "electricity," or to be left to ignorant masseurs.

Sever[1] has a series of articles on Obstetric Paralysis (Erb's Palsy) in which the literature has been gone over very carefully and he has reviewed 470 cases. He has also done a great deal of experimental work and has devised a very ingenious operation on the contracted muscles to correct some of the deformities. I will therefore quote him freely and add seventeen cases that came under my observation within the last two years, as I fully agree with an editorial writer in the *American Journal of Orthopedic Surgery* that "all cases of obstetric paralysis should be reported, especially if they came under treatment early, that the proper results can be compared."

Etiology.—The review of the literature of Sever[1] shows that the majority of observers believe that Erb's palsy is due to a stretching or tearing of some of the roots of the brachial plexus caused by forcible separation of the head and shoulders during delivery. This condition is therefore not always due to forceps, as prolonged labor or traction on the shoulders may also produce it. Thus the obstetrician is very often unjustly blamed. The ex-Kaiser Wilhelm has Erb's palsy and his mother was delivered by the famous obstetrician Jenner.

However, fracture of the clavicle or arm and epiphyseal displacement do occur and they may be associated with injury to the brachial plexus as a separate entity. One cannot accept them, however, as the sole cause of the usual type of birth palsy.

Pathology.—"There are generally two well-recognized types of paralysis seen. The more common one consists of a lesion which involves the fifth and sixth cervical roots and the suprascapular nerve and produces a paralysis of only the muscles of the upper arm with the exception of the supinators. This type is known as the upper arm type. The less usual type, the so-called lower arm or whole arm type, is the result of injury not only to the fifth and sixth cervical roots, but the seventh, eighth, and possibly the first thoracic as well. Here the whole arm is flaccid; there is a wrist drop and paralysis of the small muscles of the hand. There rarely occurs the pure lower type of paralysis without any involvement of the upper cords of the plexus, the so-called Klumpke's paralysis, several cases having been reported by J. J. Thomas, Jolly, Guillemot, Seeligmuller, Thorburn, Raymond, Comby and Danchiz. These cases show a paralysis usually the result of stretching of the plexus from overextension of the head in cases of face presentation, and due to injury to the lower cords of the plexus, namely the seventh and eighth cervical roots. They may at times be bilateral. It is in this type that one often sees inequality of the pupils owing to the fact that the sympathetic fibers from the deep cervical ganglionic plexus enter the spinal cord through the first dorsal and at times through the eighth cervical roots. Injury therefore to these roots leads to an unopposed action of the motor oculi nerve." (Sever.[1])

In describing the detailed study of the pathological findings, all quote the article by Clarke, Taylor, and Prout. Prout's description of the pathology is classic. He states[3,9]: "The nerve sheath in any overstretching process must give way before the nerve itself, as it supports the nerve. When the sheath is torn, as it always is in cases of birth palsy, the arterioles belonging to it and supported by it are ruptured, and a hemorrhage into the substance of the nerve and its sheath results. These facts are of the greatest importance, since they determine the ultimate extent and final character of the lesion. Were it not for the obstructive features of the repair process in the nerve sheath, we might expect a more or less complete recovery in the vast majority of cases. Four pathological specimens showed on study the following conditions: The usual seat of the lesion was at the junction of the fifth and sixth cervical nerves. The perineurial sheath presented many old dense pigment deposits, the site of old hemorrhages. In some persons the perineurial sheath was buckled inward on the nerve fibers, strangulating them and preventing their regeneration. Evidences of strangulation were present not only at these points, but also in the nerve fibers underlying these pigment deposits. There was an obliteration of the myelin sheath above and below. In the more severe cases the strands of the plexus involved came to an

*Read in part before Harlem Medical Association, March 5, 1919.

abrupt termination in a mass representing an old organized hemorrhage. In these cases there was a severing of the nerve fibers, which were often thrown into fold for some distance from the primary lesion. Repair of the nerve sheath takes place before regeneration of the nerve fibers, and if this has buckled inward on the nerve bundles following relief of tension, the nerve fibers are inevitably going to be strangulated and their regeneration prevented.'

T. T. Thomas of Philadelphia[11, 12] has written a great deal about a theory that the paralysis usually results from a laceration of the axillary portion of the joint capsule, following an injury to the shoulder joint itself occurring at birth. This tear in the capsule produces an inflammatory serous exudate which involves the branches of the brachial plexus adjacent. He believes that there is always in these cases a primary traumatic subluxation of the head of the humerus accompanied by laceration of the joint capsule, rather than a primary nerve lesion. Thomas fails to back up his statements with pathological evidence. The observation of others and the careful experiments carried out by Sever on the cadaver failed to prove Thomas' theory. There is no other observer to my knowledge who corroborated Thomas' statements. In my own cases I have taken special pains to examine for congenital dislocation or subluxation and have not found even one early case showing this condition.

Roentgen-Ray Findings.—"In the first year there is usually nothing seen of bony deformity. There may be a slight posterior subluxation of the shoulder joint, but there is never any acromial deformity evident by roentgenogram or clinically. No case has been observed in which the epiphysis has been displaced so far as could be seen by comparison with the normal shoulder. The epiphysis, as well as the shaft of the humerus, is always smaller than the unaffected side which condition is undoubtedly due to atrophy from disuse. The scapula is practically always elevated and outwardly rotated, due apparently to the pull of the intact inward rotators and the levator anguli scapulæ. As time goes on and the child gets older, one begins to see increasing evidences of bony deformity, occasionally more joint subluxation than at first, increasing outward displacement and elevation of the scapula, and acromial deformity. The deformity of the acromion consists of a bending downward and forward or a hooking of its outer end, which apparently having no bony resistance to meet as normally in the head of the humerus, projects downward in front of the subluxated and inwardly rotated head. This hooking seems to vary directly with the degree of posterior subluxation and inward rotation of the humerus and tends to increase as the child gets older, provided subluxation is present. No case has been observed in which there has been a total subluxation or dislocation of the shoulder joint backward. The clavicle usually is shorter and its curves are more acute than its normal fellow." (Sever.[4])

Clinical Findings.—"In the upper arm type then, the nerves involved are the suprascapular, from the fifth cervical root and outer cord of plexus, going to the supraspinatus and infraspinatus muscles. The musculocutaneous from the fifth and sixth cervical roots and outer cord of the plexus, going to the coracobrachialis biceps and brachialis anticus. The circumflex from the fifth and sixth, and possibly the seventh and eighth and posterior cord of the plexus, going to the deltoideus and teres minor. The musculospiralis from the fifth, sixth and seventh, and also possibly some fibers from the eighth cervical and posterior cord of the plexus, going to the supinator longus and brevis, brachialis, brachialis anticus, triceps, anconeus, and extensors of hand. . . . The injury to the plexus is located at about the junction of the fifth and sixth cervical nerve roots, just above the point of origin of the suprascapular nerve. This junction point is called Erb's point, from his classic description of the type of paralysis seen following injury at that point. . . . The inability to raise or abduct the arm at the shoulder is due to the paralysis of the deltoideus and supraspinatus. Outward rotation cannot be accomplished because of the paralysis of the infraspinatus and teres minor, and the arm cannot be internally rotated owing to the internal rotators, namely the teres major, subscapularis and latissimus dorsi, being already fully contracted, due to lack of opposition. The arm cannot be flexed at the elbow, owing to the paralysis or weakness of the biceps, brachialis anticus, coracobrachialis and supinator longus; and supination cannot be carried out owing partially to the inward rotation in which the arm is held and the weakness or paralysis of the biceps and supinator longus and brevis." (Sever.[4])

In regard to sensation it cannot be satisfactorily determined on account of the young age of the patient. Electrical reactions cannot conscientiously be carried out, as it would require anesthesia in making this examination, and it is doubtful whether one is justified to do that when one already has all necessary data. During the first week in the early cases, the child may cry if the arm is handled or moved, especially in abduction, but this soon disappears.

"The hand grasp is usually good and the child flexes and extends the wrist and fingers well. The later developments in the upper arm cases, as the child grows and gets older, with or without exercises and massage, are as follows: The persistence of the inward rotation and adduction deformity, the so-called policeman's tip position, the inability in most cases to fully or freely supinate, the inability to get the hand to the mouth without raising the elbow, due to inability outwardly to rotate, the inability to put the hand to the head or behind the back. In the lower arm type all these conditions hold, besides the additional ones due to the paralytic conditions of the lower arm and hand, resulting generally in a useless dangle arm. Atrophy of the muscles in these cases of obstetric paralysis is never very marked, except in some cases of the lower arm type. One never sees the extreme atrophy so noticeable in cases of infantile paralysis. This lack of marked atrophy is undoubtedly due to the fact that the nerve impulses are rarely fully blocked and that the muscles practically never, except in rare cases, wholly lose their entire enervation. Some normal nerve impulses pass through the scar tissue at the site of the lesions, owing to incomplete destruction or injury of the nerve, and so keep the muscle tone up to a certain point. There

is always a definite shortening of the arm, however in all cases, due probably as much to nerve injury as lack of use." (Sever.[4])

Complications.—1. Early. (*a*) Facial paralysis which is usually mild and in the same side as the paralyzed arm and is probably due to forceps pressure on the facial nerve.

(*b*) Fracture of the clavicle (not very rare).

(*c*) Separation of the epiphysis of the head of the humerus.

(*d*) Dislocation of the humerus (sometimes present).

(*e*) Fracture of the upper third of the humerus.

2. Late. (*a*) Posterior subluxation of the humerus which is quite common and is due to contraction of unparalyzed pectoralis major, subscapularis and teres major.

(*b*) Hooking of the acromion.

(*c*) Anterior subluxation of the humerus. This is due to the pull of the contracted pectoralis major and the stretching of the subscapularis.

(*d*) Contraction of the biceps and the brachialis anticus, leading to some degree of permanent flexion deformity at the elbow and occasionally dislocation of the head of the radius.

Diagnosis.—Though the diagnosis is easy, considering the history and remembering that the malady is usually noticed if not immediately after birth by the physician himself, then by the mother, grandmother, or nurse on the first day, still there are a few points one must bear in mind and there are a few important landmarks one must think of, so that nothing is left undone.

(*a*) Look for a fracture of the clavicle or arm or a separation of epiphysis. In addition to clinical examination one may resort to radiographic examination.

(*b*) Look for tenderness and swelling about the joint and tenderness on pressure above the clavicle over the course of the brachial plexus. Tenderness in the axilla might also indicate an exudate about the lower portion of the plexus.

(*c*) Look for inequality in pupils, as that without question implies an injury to the inner cord of the brachial plexus high enough up to cause stimulation of the sympathetic branch of the cervical sympathetic plexus, which sends off a communicating branch from the fifth cervical segment of the cord.

(*d*) Look for a dislocation or subluxation of the shoulder posteriorly, as T. T. Thomas warns.[11 & 12] Thomas gives the following sign for dislocation of the shoulder backwards or posterior subluxation: "Absence of normal roundness of the humerus immediately in front of the acromion and the presence of a small prominence just back of the acromion where there should be a slight depression." He also adds that there may be bending downward and forward of the anterior portion of the acromion, which with the posterior displacement of the humerus, is probably due to the pressure of the maternal public bone. Though Thomas's theory has not appealed to me, still I have taken great pains to follow the signs he suggested and have not found even one dislocation or subluxation. I do not intend, however, to abandon it and will continue to look for a dislocation or subluxation.

(*e*) The paralysis of the muscles that are involved should be determined as carefully as possible and the position of the limb recorded.

Differential Diagnosis.—Obstetric paralysis must be differentiated from:

1. Anterior poliomyelitis. If observed very early it may without any difficulty be recognized; the history of occurrence at birth helps in the diagnosis. If seen, say at the age of one year or later, careful examination will show the attitude of internal rotation and adduction with flexion at the elbow in Erb's, while in anterior poliomyelitis they are absent, though in some occasion there may be adduction deformity.

Wasting in anterior poliomyelitis is marked while in Erb's it is slight, due to the action of same muscles left intact as previously stated. There is no interval between the acromion and head of the humerus in Erb's, which is very common in anterior poliomyelitis due to wasting of the deltoid, allowing the upper extremity to pull and give this interspace.

Between the whole arm type of Erb and anterior poliomyelitis affecting the entire upper extremity there may sometimes be difficulty of differentiation, but the pectoralis major in most of the cases of Erb's paralysis is not involved while in poliomyelitis it is. The adduction and internal rotation is present even in whole arm paralysis though to a slight degree.

2. Spastic paralysis has so many other symptoms, as the mental complications and the spasticity of all the muscles and other limbs, that it offers very little difficulty in differentiating them.

3. Diphtheritic paralysis gives a history of diphtheria and there is absence of the attitude of adduction and internal rotation.

4. Fracture of the clavicle or arm may present obstacles as the deformity may be the same, but the *x*-ray will as usually clear up the diagnosis of the fracture. Of course both conditions may occur together.

5. Syphilitic epiphysitis. There is lacking the characteristic position of the arm, and careful examination discloses the fact that paralysis is only apparent.

Prognosis.—"The prognosis in all upper arm type of cases is good provided the case is watched from the start and treatments properly carried out. The patients are practically all able to raise the arm to the shoulder level and can use the hand and lower arm well, except for varying degrees of supination. In the lower arm type the outlook is not so good, although many of the patients regain use of the upper arm in spite of the persistent paralysis of the lower arm and hand." (Sever.[4])

Treatment.—As to treatment, the upper arm type can, if seen early, be treated with support, massage and exercises. Those of the lower arm type usually have to be operated on for the repair of the plexus. If the upper arm type comes late for treatments, one has also to operate on and correct contraction deformities. Even in lower arm type one may try for a very short time conservative treatments and if no improvements are noticed in a few weeks, operation should be resorted to. (See Case III.)

Conservative Treatment (support and exercises): In order to prevent contraction of unparalyzed mus-

cles, it seems best to put the arm at rest in such a position that the stronger muscles cannot contract. This may be done by holding the arm in a plaster cast or by the use of a light wire splint.

Position: The arm should be abducted to a right angle with the torso or perhaps a little elevated so as to approximate the injured nerve. The limb should be rotated outward and the forearm supinated. Whether the elbow is to be in a flexed or extended position is a rule hard to make. Considering that there is a tendency to contraction at the elbow, it would be proper judgment to put the elbow in full extension, but this puts the paralyzed biceps on a stretch and as is well known, a stretched muscle will not rapidly recover, hence the reversed, *i.e.* the flexed, position would be preferable.

In this series, I have treated some in flexed positions and others in extended positions. I am not prepared as yet to say which is a better one as in both the results were similar. Besides that, the choice was not made accidentally or for purely experimental purposes. For all those that had whole arm paralysis, the extended position was used while the upper arm type had the elbow in flexed position. (This series is small to draw conclusions from, but it gave me the impression that the flexed position is better.) If the arm is kept in the support between massage and gymnastic treatments, one obtains a better subsequent position of the arm. It also takes the drag off the paralyzed shoulder muscles, particularly the deltoid, allowing them to regain their strength more quickly, and prevents subsequent shoulder deformity, such as subluxation and acromial hooking and overgrowth. Those who cling to the theory of subluxation put up the arm in a different position. As I have not adhered to that theory, I have used the position described above. Of course before the plaster is applied the hand can be tied to the upper end of the crib.

Massage and exercises are of the greatest importance and should be done daily if possible. It is most unwise to allow a child to become obsessed with the fact that it has an arm which cannot be used. The exercises described by J. J. Thomas[10] are very good and can be easily followed. The details of the exercises are as follows:

(*a*) Under the age of two months one uses gentle irregular movements, carried out by the operator, and by the mother between treatments, such as moving the baby's hand and arm in various directions in imitation of voluntary movements made by the other arm.

(*b*) After two months it is advisable to bend, stretch or spread the baby's fingers while using the operator's arm in a similar way. It is best to accompany this by a nursery rhyme and the child will begin to imitate that. The hand should be flexed and extended at the wrist and then carried to the neck, thus flexing the forearm. The forearm should be abducted, adducted with the hand supinated and the elbow bent and held at the side; arm extension in supination, where with the elbow bent and at the side of the forearm, it should be rotated outwards, but within the limits of comfort; the hand in supination, the arm should be extended by the operator in the direction of the line of the forearm.

The arm should be lifted to as near a vertical position as possible, from a position of extension in supination; then from the vertical position the elbow should be lowered to the side bringing the hand to the shoulder or neck. From the position with the elbow bent and at the side the arm should be stretched out and returned, and the arm in the horizontally stretched-out position should be swung to describe a curve. These exercises are to be repeated 2 to 8 times each.

Both arms should be stretched sideways three or four times and then the hands carried to the head; the arms should be extended upward, and then returned to the bent position; the arms form a circle in front of the body, the fingers touching, and then the arms should be carried upward until the hands are over the head and then separated and lowered to the sides. For a part of each day the healthy arm should be bandaged to the body, thus forcing the baby to use his affected arm as much as possible.

At the age of 10 or 12 months it is appropriate to use blocks and perhaps put the blocks in different places and make the child reach them. One may also induce the child to put blocks in a box held at different places.

At the age of 18 months the child can perform the first group of exercises voluntarily, and dumbbells, wands, balls, bean-bags and such things could be used.

At two and a half or three years the child will swing on a bar, walk into a corner with arms spread out, creep up the wall.

The last muscles to develop are usually the outward rotators of the humerus and supinators. One may use the following exercise: with the elbow bent at the side, and the forearm in supination and abduction, with a small iron dumb-bell in the hand, the arm is extended in the direction of the line of the forearm.

For older children we may add the following exercises advocated by M. T. Sweeney:[8]

1. Wing standing; chest raising with deep breathing.

Position: Standing erect, hands on hips.

Exercise: Forcible chest elevation with deep breathing.

2. On table on back, stick raising with deep breathing.

Position: On table on back, hands well separated grasping stick.

Exercise: Stick raising over head with inhalation, sinking with exhalation.

3. Rest sitting, chest expansion.

Position: Sitting on bench, hands behind head, elbows well back, careful not to hollow back during exercise; support should be given by the operator.

Exercise: At inhalation the arms are lifted up and back and returned to starting position on exhalation. Good pull should be given to gain the desired pectoral stretch.

The following cane exercises (taken from Buchaltz's[2] book) may be added if limitation of shoulder is present or after Sever's operation. Cane held in both hands.

1. Raise cane with the arms straight.

2. Flex the elbow and lift the cane up in front of the chest; from this position the cane is brought forward or upward or to any angle desired.

3. One end of the cane is raised up over one side of the body while the other is placed on the other side.

4. The cane is held in front of the chin with the hands about three feet apart; then it is moved horizontally toward one side and then the other. This exercise can also be done with the cane on the back of the neck.

5. The cane is held on the back, then the affected arm is raised up as high as possible and the patient has to bring scapula, elbow and wrist as much as possible in a straight line, pressing these three points against the cane.

In this exercise the affected arm extends actively, the other hand pushes passively, and both together force the shoulder and the elbow in a straight line.

Forcible Correction.—Where subluxation or dislocation does exist it should be reduced. The method of treatment of the displaced humerus as described by Whitman[13] is as follows: "The child having been anesthetized is brought to the edge of the table. The shoulder is grasped firmly with one hand in order to restrain the movements of the scapula, and with the other the arm is drawn upward and backward over the fulcrum of the thumb, which lies behind the joint. This, the so-called pump handle movement, alternately relaxing and stretching the contracted parts, is carried out over and over again with slowly increasing force, the aim being to force the head of the bone forward, and thus to thoroughly stretch the anterior part of the capsule. When this has been accomplished, there is a distinct depression behind, and the head of the humerus projects in front, at a point below its proper position.

"One then attempts to overcome the abduction and to force the head upward by changing the grasp on the scapula and using the thumb in the axilla as a fulcrum. When the arm can be carried across the chest the normal degree of adduction, the final, and often most difficult, part of the process, namely to stretch the tissue sufficiently to permit the proper degree of outward rotation, is undertaken. This is best accomplished by flexing the forearm and using this to exert leverage on the humerus, care being taken of course to avoid the danger of fracture. When the head of the bone has been replaced, it will be noted that the tension on the anterior tissues causes flexion of the forearm; this must be overcome in the same manner, and finally, the limitation to complete supination. The extremity is then fixed in the overcorrected attitude by means of a plaster support which includes the thorax. That is the arm is drawn backward so that the head of the humerus is made prominent anteriorly, the forearm is flexed and turned outward to the frontal plane, while the hand is placed in extreme supination, the upper arm lying against the lateral thoracic wall.

"In the very resistant cases it is impracticable to complete the operation at one sitting. When, therefore, as much force has been exercised as seems wise, a plaster bandage is applied to hold the arm in an intermediate position with the head of the humerus forced forward, and after an interval of two or more weeks the further correction is undertaken. In the treatment of older subjects the forcible manipulation may be preceded or supplemented by division of resistant parts." (Sever's operation.)

Tenotomy of Contracted Muscles.—If contractions at shoulder are present one may try at first forcible stretching under anesthesia following the steps of Whitman as described above, but it is much more advisable to do an open tenotomy. Sever has recently described an excellent operation to counteract the contracted pectoralis major, teres major and subscapularis, and it is really remarkable to see the improvements one obtains by this method.

Procedure: "An incision is made situated on the anterior aspect of the arm and extending from the clavicoacromial joint to a point below the lower edge of the pectoralis major tendon. The incision is carried down between the deltoid and clavicular portions of the pectoralis major, tying or retracting the cephalic vein. The tendon of the pectoralis major is isolated and divided on a director. Turning the cut pectoralis major back and retracting the deltoideus gives a good view of the long head of the biceps and the joint capsule, as well as the short head of the biceps and the coracobrachialis. The arm is now abducted and outwardly rotated, bringing into view the transverse fibers of the tendon of the subscapularis at its point of insertion into the joint capsule at its inner and anterior aspect. This tendon is isolated and a sound or other blunt instrument is passed under it, and it is then divided. In this way not only is the pectoral divided, which, when contracted, prevents abduction, but also the subscapularis is divided, which, when contracted, prevents outward rotation. It is better to divide the subscapularis by this method, rather than to open the joint capsule after Fairbank's method, for it does not lead to subsequent adhesion of the capsule to the joint cartilage and consequent loss of motion.

"After these two structures have been cut, outward rotation and abduction will usually be found to be perfectly free. In case either is at all restricted, the coracobrachialis or the short head of the biceps may be found to be tight, and the partial division of these structures will always lead to full freedom in outward rotation and abduction. If the head of the humerus is blocked by the hooking downward of the acromion in front of it, so that the posterior subluxation cannot be fully reduced, an osteotomy can be easily done on the acromion, through the upper end of the original incision.

"If there is an anterior subluxation of the joint, which occurs rarely, the pectoralis major is the only muscle which needs to be divided. A division of the subscapularis would only tend to increase a deformity already present. The pectoralis major and deltoideus are then joined with interrupted catgut sutures, and the skin closed by a continuous catgut suture. The arm is then put into a plaster cast extending from the crest of the ilium to the tips of the fingers, the arm being abducted, elevated, outwardly rotated and the hand supinated. This cast should be worn only about two weeks, at the end of which time baking, massage and exercises should be started and continued daily for several months. After two or three weeks a wire splint may be substituted for the cast, in that it is lighter and more comfortable." (Sever.[4])

Operation on the Plexus.—Repair of obstetrical

injury to the brachial plexus is often however necessary. Kennedy's method, as modified slightly by A. S. Taylor, is described by the latter as follows:

"The patient is anesthetized and brought to the table with the field prepared for operation. A firm cushion is placed beneath the shoulders, the neck is moderately extended and the face turned to the sound side. The incision passes from the posterior border of the sternomastoid muscle, at the junction of its middle and lower thirds, downward and outward to the clavicle at the junction of its middle and outer thirds. After the skin, platysma and deep fascia are divided, the omohyoid muscle is exposed near the clavicle, and lying beneath it are the suprascapular vessels. These structures may be retracted downward, or, if the case requires the extra room, the omohyoid may be divided, and then the vessels cut between double ligatures. The transversalis colli vessels are seen a little below the middle of the wound and are divided between double ligatures. The dissection is rapidly carried through the fat layer to the deep cervical fascia covering the brachial plexus, which fascia is usually thickened and adherent to the damaged nerve roots. This fascia is divided in the line of the original incision and is dissected away for the free exposure of the nerves. The damaged nerves are usually noticeably thickened and of greater density than normal nerves. The extent and distribution of the paralysis determined before operation, gives the clue as to which nerves are at fault. Usually the junction of the fifth and sixth roots is the site of maximum damage. The thickened indurated areas are determined by palpation and are excised by means of a sharp scalpel. Scissors should never be used for this work.

"The nerve ends are brought into a position by lateral sutures of fine silk involving the nerve sheaths only, while the neck and shoulder are approximated to prevent tension on the sutures. Cargile membrane is wrapped around the anastomosis to prevent connective tissue ingrowth. The omohyoid muscle, if divided, is sutured. The wound is closed with silk. A fine sterile dressing is applied, and a bandage is applied to approximate head and shoulders so as to prevent tension on the nerve sutures. This position must be maintained for at least three weeks. The most feasible method of accomplishing this result is a plaster-of-paris support placed on the child and allowed to harden in the proper position before operation. It is then trimmed and removed. When the nerve suturing is finished, the splint is slipped on, the wound is then closed, the dressing applied, and the child put to bed without danger of pulling the nerve ends apart." (Taylor.[9])

Of course where contractions are present one should correct them either by forcible correction or by Sever's operation before suturing the plexus.

Other Operative Means.—There are two or three other operations sometimes done in obstetric palsy and I will describe them briefly:

1. Osteotomy of the humerus to correct inward rotation of the shoulder. The method in short is as follows: "Patient on his back, close to the opposite edge of the operating table, operator on the side affected. An incision one inch long, just above the junction of the upper and middle third of the outer aspect of the upper arm or in the upper part of the lower third, skin incised and retracted, fat and muscles fibers are separated by a blunt dissector and retracted exposing the bone. An osteotome is then applied to the bone and the bone completely cut through. Of course he must assure himself that his assistant is steadying the elbow and forearm in order to allow no displacement. Skin closed. Coaptation splints applied then the arm is gently rotated outward about thirty degrees. A plaster-of-paris bandage is applied holding the arm and forearm at right angles. Over this a snug swathe is applied holding the plaster at the shoulder and the elbow to the side.

"The patient is kept in bed about ten days using a low bed rest constantly. The bed rest is raised for meals after the first week. The outward rotation is maintained for six or eight weeks, allowing use of the hand in the third week. The apparatus is removed a little each day after the sixth week. If the union is soft, the apparatus should remain longer. After the eighth week the apparatus is worn part of each day and a belt apparatus maintains the outward rotation of the shoulder and allows the use of the arm and hand. In extreme cases an apparatus is necessary for a year, muscle stretching and muscle training should be done twice daily as long as there is any tendency of the muscles to recontract." (Soutter.[7])

Where the acromion is depressed an osteotomy has to be done. Method: "An osteotomy is used to incise the skin one and one-half inches from the tip of the acromion, a subcutaneous osteotomy of the acromion is done, allowing the depression to be corrected and the humerus to slide into place. One suture is often necessary. The shoulder is held outwardly rotated ninety degrees and abducted ninety degrees, for six weeks." —(Soutter.)

Transplantation of the pectoral or the trapezius into the deltoid. There are many diverse methods and I will refer the reader to orthopedic text-books.

Case I.—H. A., male, first-born child, referred by Dr. Ballin to me on February 7, 1918, at the age of three weeks. The labor was prolonged; forceps had to be used. Soon after the delivery, paralysis of the right upper extremity was noticed. Slight massage was given for the three weeks and no improvements observed.

My examination showed the right arm lying limp at the side, internally rotated and adducted, elbow flexed, and hyperextension of the wrist. No power in the muscles of the upper extremity could be elicited, though very slight power could be detected in the fingers. Very slight contraction of the pectoralis major. The extensive paralysis gave, therefore, the impression of a whole arm paralysis. No subluxation or dislocation was present. The contractions being slight, were easily corrected, and a plaster cast was applied embracing the thorax and the paralyzed limb. The limb was put in a position of marked abduction, elevation, and outward rotation, elbow extended, forearm supinated, and wrist straight.

The cast was left on for five days, when it was split open and made into removable splints to be removed only for massage and exercises. When the cast was opened for the first time I was surprised at the gain of power. The fingers moved freely, though there was still a tendency to hyperextension. Child could abduct and adduct the limb, and made some attempt to raise the shoulder if the lower half of the cast was left on. Massage was given daily for three weeks, when exercises were added.

TABLE I.—REPORT OF THE FIFTEEN PATIENTS OF OBSTETRIC PARALYSIS.

PART 1.—PATIENT RECEIVING TREATMENT.

Case.	Name.	Sex.	Age Seen.	Side Affected.			Another Member in Family Affected.	History of Labor.			Child in the Family.	Type.		Complete Paralysis at Birth		Partial Recovery		Total Recovery. Operations in Cases 11 and 15 were performed by same surgeon; no orthopedic treatment.

In the third month we began to flex the elbow passively. By that time motion in the fingers was good; when the child was supine, abduction and adduction were good, but arm could not be raised more than to a right angle with the torso. Supinators—weak.

In the fourth month a new plaster splint was made. This was left off for part of the day, and toward the end of the fourth month it was left off for the entire day, while for the night only the lower half of the splint was applied.

He was treated regularly thrice a week till September, 1918, *i.e.* for five months, by massage and exercises. No electricity in any form was being used. He was discharged in September with a complete recovery. The last functions to return were the supination and hyperabduction. The mother was advised to continue the treatments herself and come only for observation. When I saw the child in March, 1919, it was hard to recognize which hand was paralyzed. There was, however, a very slight atrophy.

Thus we have a child that would probably have remained with paralysis of the lower type, regain full function by administering massage and exercises, by guarding mainly against deformities, facilitating regeneration of nerves, and preventing of undue stretching of denervated muscles.

CASE II.—S. F., female, referred to me on November 17, 1918, by Dr. Ginsberg, at the age of three weeks. Child is the fourth in the family. The others are normal. This labor was somewhat prolonged; breech presentation, but forceps had to be used; slight traction in the shoulders. Immediately after birth, bilateral paralysis of both upper extremities was noticed. She was treated with massage and slight improvement was observed in the left arm.

Physical examination on November 17, 1918, showed: Right arm—complete paralysis of all the muscles in the shoulder; partial paralysis of the fingers, forearm, and elbow. The limb kept internally adducted and rotated. The wrist slightly flexed. The left hand—paralysis of the shoulder muscles only partially, *i.e.* the patient could bring up the arm to an angle of 70°, and made an attempt to rotate it outward, but was not successful. The elbow, wrist, and fingers showed fair motion. There was a marked lump on the left side of the neck which I took for a ruptured sternocleidomastoid. This tumor was very tender and indicated, there-

fore, that there was a mechanical injury to the plexus, though the left side happened to be the one less affected. No dislocation or subluxation of either shoulder found. *X*-ray of both shoulders was negative as to the presence of a fracture or abnormality.

A plaster splint similar to the one of Case I applied, of course taking in both hands. The splint was opened on the eighth day. The improvement in the right hand (the worse one) was just as astonishing as in the former case. The same details in treatments were carried out as in Case I, but as the mother had four children to attend she left off the plaster for longer periods during the day.

The left hand recovered completetly in two months, while the right hand recovered only after six months' treatments. The last motions to return were outward rotation and supination. In this case it took rather a long time before the elbow could be flexed completely, and it seemed to me that it was advisable to begin the passive motion earlier than the third month, as I was accustomed to do.

The rapid recovery in the left hand may not be entirely attributed to the support as the limb was improving before; but the recovery without any deformity and the similar good result in the right limb which was quite severely attacked, can certainly be attributed to the proper splinting.

Case III.—W. B., male, came under my observation at Fordham Hospital at the age of six months. Child was the second one in the family. No forceps were applied, but the labor was prolonged. Paralysis of the right arm was noticed immediately after birth, but no treatments given.

Examination showed: Arm limp at the side, inwardly rotated, adducted, forearm flexed, and wrist drop present. Complete inability to abduct, elevate, outwardly rotate, or supinate. No motion in the fingers. No dislocation of the shoulder present.

A brace similar to the plaster was applied, but the hand could not be put in the proper position on account of the contracted muscles (pectoralis major, etc.) and only slight correction obtained in the brace. Massage and exercises were given for four weeks, but very little improvement resulted. It was decided then that it would be better to operate. The operation was done in the First Surgical Division of Fordham Hospital by Dr. A. S. Taylor and myself. Sever's operation was first performed (cutting the pectoralis major, teres major, and subscapularis). The limb could then easily be rotated outward and abducted. The brachial plexus was then exposed and the fifth and sixth roots were found seriously damaged, forming two masses connected by a narrow isthmus of connective tissue. The scar tissue was excised for a distance of 3 cm. till good nerve bundles were found. An end to end anastomosis was then done.

After the operation the brace was reapplied with the arm markedly elevated, touching almost the head. Massage and exercises began on the eleventh day. Brace was worn continuously for nine months.

After one year he had good power in the fingers, elbow, and shoulder. Outward rotation still weak. Supination also less than normal. No contraction present. The child has passed out of observation and we have not been able to trace him.

The contraction of the muscles was present even in the first half year. The plexus was injured extensively hence our conservative treatment was of very little benefit and an operation had to be resorted to.

The excellent results of Sever's and Taylor's operations indicate that no time should be lost in performing these if conservative treatments fail. It is particularly well to perform both operations at one sitting so as not to lose time. If the nerves are found intact, no damage is done by the skin incision.

Case IV.—H. K., male, sent to Fordham Hospital by Dr. R. H. Sayre on March 4, 1919, at the age of seven weeks. Child is the fifth in the family. He has one older brother with a similar affection. (See Case VIII.)

This child was delivered without forceps. Vertex presentation, but slight traction was applied to the shoulder at the delivery. (It is, however, doubtful whether the traction has really produced it as there is already one in the family with a similar affection.) Soon after birth it was noticed that the child could not use the right upper extremity. Nothing was done for the child till seen by Dr. Sayre, who referred the case to me at Fordham Hospital on account of nearness of the hospital to the mothers' residence. Child had not improved during the interval.

Physical examination on March 4, 1919: The right limb held in inward rotation and adduction. No power in the shoulder muscles. Elbow was straight. Wrist in normal position. There was slight power in the fingers. At the first glance it was thought that there was a dislocation forward of the head of the humerus, but careful examination by several competent men proved that the shoulder was only rotated inward and adducted by the contracted pectoralis muscle. The *x*-ray gave very little clue as to the presence or absence of dislocation.

The child was put in a plaster splint with the limb abducted to a right angle with the torso, outwardly rotated while the forearm flexed, as it was considered that there was no fear of contraction of the biceps and it might, on the contrary, give a better chance for complete recovery of the biceps.

The plaster was removed after two weeks and the improvement in all the muscles was marked. At present the child is getting massage and exercises, and is still kept in the plaster splint. The improvements thus far observed are very gratifying.

This case indicates the necessity of very careful observation to determine whether there is a congenital dislocation of the shoulder or not, for sometimes there may appear to be a dislocation whereas, in fact, it is not. The contraction of the pectoralis major was present even at such an early age. The improvements were remarkable even after such a delay.

Case V.—A. N., female, first child, came under my observation at Fordham Hospital on May 1, 1919, at the age of one month. No forceps were used; vertex presentation, but the cord was around the hand. (Case delivered by a midwife.) About two days after birth it was noticed that the child could not use the right hand. No treatments were given, but the hand was improving gradually.

Physical examination: The shoulder muscles were partially paralyzed, but not completely; could bring the hand to the mouth; had easy use of fingers and elbow. The limb was kept adducted and internally rotated. No subluxation or dislocation present.

Treatment: Applied a plaster splint on May 3, with the arm at right angle and elbow flexed. The splint was opened on May 15 and marked improvement was found.

This child apparently has very little damage to the plexus, but if it will not be guarded, the deltoid will stretch and the entire limb will be adducted and rotated inward.

Case VI.—M. S., male, referred to me by Dr. Rubinstein on January 20, 1917, at the age of three and one-half years. Child is the second in the family. Forceps delivery. Paralysis of left upper extremity noticed right after birth. Treated with massage and exercises; very little improvement noticed.

Physical examination: Left upper extremity internally rotated, but not markedly adducted; elbow flexed; can abduct arm to an angle of 45°; external rotation *nil*. Limb shorter three-quarters. Power in fingers good. As the contractions were not marked, no Sever's operation seemed necessary. The shoulder was stretched and rotated outward, and a brace applied to be worn contin-

uously day and night and to be removed only for massage and exercises.

After three months patient showed marked improvement, could abduct the arm and rotate it quite a great deal, could touch the back of his head. Advised to wear the brace for a long time and carry on regular exercises for two or three years.

This case indicates the great value of prevention of deformities and the rapidity of improvement if the contractions are stretched.

Case VII.—P. E., female, referred to me by Dr. Freid on May 27, 1918, at the age of two and one-half years. Child is the first born; difficult labor; forceps. Immediately after birth paralysis of left upper extremity was noticed. She was treated by another orthopedic surgeon all the time with massage and electricity, and no attention was paid to prevent the deformities. When she came under my observation she had all the typical deformities of the shoulder and elbow which I have enumerated before. No power in the shoulder at all. The finger motions were good.

As the contractures were marked Sever's operation was advised, but the parents were against it. The child was anesthetized and the shoulder stretched and rotated outward to tear up some of the adhesions. A plaster splint was then applied, keeping the arm markedly abducted and elevated and rotated outward, the elbow straight and supinated. The plaster was removed at the end of two weeks, a similar brace was then applied, and massage with proper exercises began.

The improvement was marked. After four months' treatments she could raise the shoulder to a right angle when in a supine position, could rotate the shoulder outward, and touch the top of her head. She is improving nicely.

The rapid improvement after stretching only, followed by proper exercises, shows that the damage to the nerves was not too severe and had she been treated properly from the beginning with proper support and exercises she would have made a perfect recovery.

The other cases on Table I have only consulted me, but no treatment was given. Either the parents refused an operation or did not consult me after the first examination.

Table II.—Summary of Conditions Existing at Birth in Seventeen Cases (Fifteen Patients).

Boys	8	Head presentation (including face)	13
Girls	7	Breech presentation (including feet and version)	2
Right arm affected	7	Cord around arm	1
Left arm affected	6	Patients treated	7
Both arms affected	4	Conditions at present:	
Upper arm type	7	Cured	2
Lower or whole arm type	6	Improved	5
Difficult labor	13	Unimproved	0
Forceps used	8		
Normal labor	1		

Conclusions.—1. Obstetric palsy belongs to the domain of orthopedic surgery as any other congenital deformity of a limb.

2. Obstetric palsy should be treated on the same principle as anterior poliomyelitis and all the deformities should be watched and prevented.

3. The principle in peripheral nerve injuries to prevent over-stretching and over-use of the denervated muscles should be applied here and the weak muscle watched.

4. The shoulder should be put immediately in a splint or brace to prevent stretching of the deltoid and allow absorption of hemorrhage and repair of the damaged nerves.

5. In most of the cases the injuries to the nerves are not severe and if treated early will recover.

6. About three months may be allowed for conservative treatments in the early cases. If no marked improvement is obtained, an operation on the plexus should be resorted to.

7. Conservative treatments consist of: Proper support, massage and exercises. No use of resorting to the universal panacea "electricity."

8. Taylor's operation on the plexus is very useful and should be performed after the conservative treatments have failed.

9. The contracted pectoralis major, subscapularis and teres major should be cut by Sever's method if effectual results be desirable.

10. A patient suffering from this affection should be under proper observation at least till the age of ten as slight deformity may persist.

I wish to express my thanks to the physicians for their kindness in permitting me to study these cases and to Dr. Joseph Byrne for the neurological examinations made in some of these cases.

ACONITE IN THE TREATMENT OF EPIDEMIC INFLUENZA.

By SPENCER G. STRAUSS, A.B., M.D.,

NEW YORK.

LIEUT. M.C., U.S.N.R.F.,

Perhaps there is nothing new under the sun. In searching back over fields of knowledge one often rediscovers. Facts of value are too frequently forgotten in the mad human rush to advance. Ideas which for years have slept a smothering sleep under the odious influence of being held "old fashioned" are sometimes revitalized, and this thought-crystal long dust-covered will, when led again into the sunlight of activity, shine forth refreshed, and, reflecting all the purest colors of the spectrum, become a beacon light, brilliantly adorned

in a new setting, to guide the intellectual voyager. Like wine, does human thought, with age, often grow more subtle in its fragrance and more far-reaching in its sphere of influence.

We find that *Aconitum napellus* is one of the best known species of the Aconitum genus of plants, containing in its root 0.5 per cent. of the alkaloid aconitine. In therapeutic doses it acts on the heart by stimulating the vagus centre, causing a greater contraction in systole, a greater relaxation in diastole and a slowing of the pulse rate. This effect with the probable arteriole dilatation which follows its therapeutic use results in a freer circulation of blood through the body, which means that the inherent antitoxic qualities of the blood are able to exert a greater protective influence against invading toxins.

One hundred and sixty-four consecutive cases of influenza, in the epidemic of last year, were treated by me with aconite alone, and none died excepting when a complicating pneumonia developed.

In judging the value of a remedy one must know about the material treated. What was its source? What was the intensity of the individual case? Whether they were "suitable and selected" as is the misleading fact in so many reports of successful therapeutic effort. I shall cover these points.

During the influenza pandemic of 1918 I was fortunate enough to have full charge of two wards at the United States Naval Hospital, Pelham Bay Park, N. Y. The therapeutic routine for these cases was left entirely in my hands. As was the custom in so many Army and Navy base hospitals which were temporarily erected to meet the war emergency, the wards of this institution were constructed separately, one ward to a building. Naturally the free ventilation, which was made possible by the fact of there being windows on all four sides, was of a particular advantage in handling this malignant epidemic. A second advantage was the fact that the patients were carried from the ambulances which brought them to the hospital to their beds with great rapidity and ease.

The cases I handled all came from the United States Naval Training Station a quarter of a mile away. Upon discovering a man suffering with the symptoms of influenza, a member of the Staff of Medical Officers in the Training Camp immediately put the patient to bed in temporary camp infirmaries and notified the base hospital by telephone to send for the patient. One of the dozen different ambulances started off for the patient upon receipt of such a message.

As the base hospital was situated adjacent to the training camp it frequently developed that the patient would be in his bed, in the hospital, fifteen minutes after the appearance of his first symptoms. This was not only a tremendous advantage to the patient, inasmuch as he was placed on hospital treatment almost immediately, but it acted as a means of preventing the spread of this disease in the training camp; while further, and most important, it enabled the hospital medical officer to carry out his therapeutic plans from the onset of the illness. So we received for treatment in the hospital very few patients who had previously been given drugs of any description.

Each morning the hospital medical officers reported the number of vacant beds in the wards under their charge and as the patients arrived they were distributed evenly through these vacancies. This was done in order to hold the various wards of the hospital equally filled. The ambulance driver was informed of the ultimate destination of the patient before he started. In this way a great deal of time was saved. I mention this distribution of the cases so that the reader will know that the severity of the cases each individual officer treated was a matter of chance.

My wards normally held twenty-eight to thirty-two beds, but at the height of this epidemic they were so crowded that I had to fill them to twice their normal capacity. In each ward the work was done by two female nurses and four to six male hospital corpsmen. In view of the crowding and the limited help available, here as everywhere throughout the country, it was not always possible to give each patient the most ideal care, and naturally special emphasis was laid on those most seriously ill.

The most difficult problem which confronted me was how to treat these cases. At the time of the epidemic it was difficult to tell which course to pursue as I had no similar previous experience to base my decision on and the exact nature of this disease was a more or less unknown quantity. I realized, that in order to have valuable information which could be used in any similar future crisis, the most reasonable scheme of treatment was to divide my cases into groups, and in each group to carry out a different therapeutic plan.

The epidemic overcome, I have group statistics which, in their comparison, show the relative value of various therapeutic ideas positively. In order to handle these cases intelligently it was always necessary to distinguish clearly, from the start, whether there was any pneumonic involvement or not. On account of its frequency in the course of this disease, I have almost come to regard a bronchopneumonic development as a normal feature of this influenza, but inasmuch as most observers regard the pneumonias as complications of this disease, I shall so regard them in this paper as I did in my original therapeutic endeavor. After a careful comparison of the above mentioned group statistics, the scheme which showed up best was the following:

Attendants.—The nurses and corpsmen in charge of the patients wore ordinary operating room gowns and operating room caps and continually had their noses and mouths covered by a double layer of gauze. There is no doubt that the gauze acted as a successful mechanical filter, holding out many bacteria from the inspired air and in handling patients, ill with a disease so frequently accompanied by a productive cough, such filtration must be regarded as of special value. But of greater importance, by far, was the fact that the unusual presence of a gauze mask had a most beneficial psychological effect on the nursing staff. The mask, unpleasant as it was to wear, was a continuous silent warning of danger and so were the attendants not only more careful of themselves but strove more conscientiously to meet fully their pa-

tients' needs. This protective dress was replaced by a fresh one each morning. The corpsmen were instructed to rinse their hands carefully in a bichloride of mercury solution after tending each patient. These methods were used more to prevent the staff from contracting the disease than for any other reason, but there can be no doubt that a fresh clothing outfit each day was prophylactic so far as cross infections were concerned. Each corpsman was assigned a definite number of patients to whom he served meals and medicine. In this way undue moving about through the wards was prevented and the danger of cross infection was further reduced. The dishes and utensils of each patient were sterilized by boiling after each meal, and the excreta were either destroyed by burning or thoroughly sterilized by chemical means.

Therapeusis.—Upon admission each patient was given one and a half ounces of castor oil. I felt this was necessary, because among young men in service training camps dietary indiscretions are so very frequent. This was the only cathartic medication the patient received. Thereafter, the lower bowel was cleansed each day by a simple soap-suds enema given each morning, unless there was a natural action.

After the cathartic action of the castor oil was established each man received the following: Three minims of tincture of aconite, U.S.P., were mixed in four ounces of water. This mixture was given in doses of one teaspoonful every half hour until the entire solution was used. This was repeated until the temperature was reduce to 99° F. (through the second to fourth day of the illness), but no patient was allowed to receive more than nine minims of the tincture of aconite in such solution. No other medication was used. The patients were kept in their beds seven days after their temperature remained normal throughout a twenty-four hour period, and were then allowed up a gradually increasing time for three days, and after four more days of full convalescence were discharged. One cannot overemphasize the importance of complete rest until convalescence is nearly complete.

During the febrile period the diet consisted of strained soups, strained cooked cereals, and albumen water flavored with lemon juice and sugar. Inasmuch as this was an acute disease of very short duration the limited diet was sufficient. Milk and milk foods were avoided during the febrile period. The sick were encouraged to drink cool water frequently. To those patients who were accustomed to the use of alcohol, two ounces of whiskey were given each twenty-four hours. After the fever subsided the diet was gradually returned to normal.

One hundred and sixty-four consecutive cases as they came into my wards were treated in this way. Of these cases thirty-one developed pneumonia of which two died. In other words:

Proportion of cases developing pneumonia.. 18.9%
Proportion of pneumonia cases that died.... 6.4%
Proportion of total group that died..... 1.2%

There were no deaths from influenza uncomplicated by pneumonia in this group.

A review of the daily average temperature curves of the uncomplicated influenza cases revealed the following:

First Day: Between 101° F. and 105° F., Average 103° F.

Second Day: Between 99° F. and 103° F. Average 101° F.

Third Day: Thirty-four cases returned to normal.

Fourth Day: Forty-four cases returned to normal.

A secondary rise in temperature was noted in twenty-four cases. This took place usually in the third twenty-four hour period. When this happened, the aconite solution was again given. Including these cases, all of the series showed a normal temperature by the sixth day.

The pneumonia cases developing in this group seemed to do particularly well with hypodermic injections of adrenalin chloride, 8 minims to the dose, every three hours; and of the digitalis preparations used on these cases, digalen was the most beneficial.

The simplicity of this treatment must make an immediate appeal; one great advantage being that the patient is not overloaded with many drugs of various types. Specifically its advantages appear to be as follows:

Summary.—1. The exertion of a particular rapid action upon the febrile course of this influenzal infection by tincture of aconite in solution; bringing about a recovery more quickly than was usual with other methods of treatment.

2. The relative number of cases developing pneumonic complications was lower than that among cases treated by other methods.

3. The pneumonias were, as a whole, milder in their clinical course than those developing in differently treated groups. This is shown by the low pneumonia mortality figures above.

4. There was a total absence of any complications, except the pneumonias, in this series.

5. None of the pneumonias developed a complicating empyema.

Whether tincture of aconite acts differently when given diluted, as I have indicated, than it does when given in the usual way, I am not prepared, definitively, to answer, but the above analysis would make it appear that this is the case.

ABSOLUTE REST AS A METABOLIC STIMULANT.

By William H. Porter, M.D.,

New York.

Emeritus Professor of Pathology and General Medicine, New York Post-Graduate Medical School and Hospital

Do the nervous systems of some patients require the anodyne of complete relief from functioning before their physiological processes are rehabilitated? And is normal metabolism favored by this state of absolute inertia?

I have had at least two experiences which incline me to believe that such may be the case. Possibly a more extended trial of the method might result in developing a new technique in handling hitherto intractable dyscrasias.

However, here is the story. Judge for yourself.

About forty years ago I was called in to see an old

minister in our town who was suffering from a most distressing and soul-harrowing case of eczema. For two weeks this man had not slept more than an hour or two at a time, except when under the influence of full doses of bromides. As may be imagined he was a physical and mental wreck, threatening suicide in such a dramatic and desperate manner as to be a constant source of solicitude to his family.

About this time I read, in the first edition of Wood's *Therapeutics* and *Principles of Practice*, that the alkaloid aconitine was most effective in peripheral nerve irritations, used locally in an unguent. I ordered a prescription containing 1 grain of aconitine in a dram of lard, and personally rubbed the entire dram most carefully and completely into the old minister's eczematous face. Almost instantly the irritation was relieved. The nervous system was completely relaxed. The old gentleman immediately lay down on the bed with all his clothes on and fell into the deep sleep of exhaustion. He slept uninterruptedly for eighteen hours, after which time he awoke naturally, and expressed himself as "feeling fine." He was entirely relieved of his distressing itching, and there was thereafter a progressive and continual improvement under ordinary local and constitutional measures. The patient was discharged as cured within a very few weeks and had no recurrence of the condition, so far as I was able to learn.

Desperate remedies are justified by desperate cases. Fortunately, the physician rarely meets conditions that require such superheroic treatment.

So it was not until forty years later that the long arm of coincidence produced another such result—and strangely enough, also in an eczema patient.

This patient was a woman, of fifty odd years, suffering from a most serious and sleep-killing eczema, affecting the vulva, anus, interior aspect of the thighs, and the entire perineal region. She scratched so industriously and energetically that the muscular tissue in her hands actually became thin and clawlike—like those of a person who had been ill for a long time with some wasting disease. This woman was a most proper and dignified maiden lady when she wasn't scratching. But when the impulse manifested itself—which was mostly all the time—"she was absolutely lost to all sense of modesty," as she herself put it.

It may be interesting to note here that this lady had been treated for Riggs' disease some months before, a condition from which she had suffered for some considerable time. This was practically cleared up, however, under local treatment by a good dentist. In conjunction with the pyorrhea she also had a suppurative postnasal and pharyngeal catarrh, with a most offensive odor. A course of treatment with liquid iodex, through the nose and postnasally through the mouth, cleared up this trouble in a month or thereabouts.

Then, following a nervous and physical debauch of Red Cross and other war work, she developed the eczema. This continued for about four months, irrespective of any and all kinds of treatment attempted.

About this time the patient, by mistake in the directions, took three twenty-grain doses of veronal with a tenth of a grain of extract of hyocyamus to each dose—all between the hours of 8 A. M. and 12 P. M. The result was that she fell into a deep sleep—almost a coma—and slept for thirty-six hours, awakening only at intervals to micturate, or to take an occasional sip of water. She could be roused at any time, but much preferred to be let alone.

Following this she had the most intense nausea and vomiting and a great deal of pain in the gastric and hepatic regions. This lasted about forty-eight hours, and was finally brought under control by mercurial purgation and the free administration of a saturated solution of chloretone—a tablespoonful every fifteen minutes or half hour, as the condition seemed to demand. Also I had the idea that chloretone, being a nerve sedative, would influence favorably the local eczematous condition. After these doses of the hypnotic and the subsequent gastric and hepatic attack, the local eczematous condition began to improve—to respond to local and systematic treatment.

About a week later my attention was called to the very interesting effects of medication by nonspecific proteins. While proteal—as it is called by its discoverer, Dr. Henry Smith Williams, is not specifically recommended in the treatment of eczema, I concluded that eczema, being a metabolic disturbance, should be favorably influenced by a form of treatment which had shown such excellent results in depraved metabolism. I therefore administered proteal, commencing with ten minim doses every other day, gradually increasing to thirty minims. This was continued for ten days, when a painful wheal developed on the arm, and the use of proteal was temporarily suspended. During the ten days in which proteal was exhibited there was a decided recession in the local irritation. But after suspending the proteal the local irritation increased again. Proteal was therefore resumed, deep muscular injections being given, this time, instead of the subdermal injections which Dr. Williams recommends.

My reason for reverting to my former practice of deep injections instead of hypodermics, is that, in my experience, the subcutaneus method is quite likely to develop local tendernesses, abscesses or ulcers, while the deep injection, being made into more active functioning tissue, rarely or never causes these troubles.

The eczematous condition modified, and finally went to complete and ultimate recovery.

The natural conclusion to be drawn from these two cases is that there are conditions in which nothing helpful can be done unless the nervous system can first be given a period of absolute rest. Then these patients pick up and yield to the ordinary lines of well-selected treatment.

In my opinion the reason for this lies in the fact that nature during a period of absolute rest rehabilitates not only the nervous system, but also the general metabolism, and this results in the correction of dyscrasias that otherwise might prove altogehter unyielding. In any event, the theory has worked twice. There is no reason to believe that it might not be coaxed into becoming routine.

46 WEST EIGHTY-THIRD STREET.

MEDICAL NEOLOGISMS OF RABELAIS.

By DOUGLAS W. MONTGOMERY, M.D.,

SAN FRANCISCO, CALIF.

HENRI CLOUZOT, in speaking of Rabelais' genius in the employment of words, says that he made use of slang, words from foreign languages, and old Gallic expressions of the Middle Ages. If words already employed failed him, he invented new ones, and these were so well composed that they immediately became incorporated in the living French language of his day.[1] We may also add that these terms which Rabelais introduced into the French language found their way into English, and often with the very meanings which Rabelais attached to them.

To understand Rabelais' position in regard to the French language one must consider his ideals and the time in which he lived. Rome was the center of the world, and Latin was the language of the cultivated. French and German were the languages of the people, and "the people" was a despised and ignorant mass, with no political outlook. Cities, it is true, with special privileges, were scattered over the countries, like little republics, but they were almost entirely occupied with their local affairs, or, like Lyons, and Frankfort, were market centers, interested only in commerce. Under such circumstances the learned were proud of their learning, and especially of their Latin, by which they were

brought into close communion with Rome, with the great Roman Catholic Church, and with the learned men all over the civilized world. The people, however, were beginning to count for something, both in France and in Germany, and politicians, in order to reach them, had to speak to them in the language of their heart and sentiments. Luther translated the Bible into German, and the very prim, erudite Calvin wrote in French, and so, together with Rabelais, became one of the founders of the French language.

Rabelais was of a different stamp from either Luther or Calvin, whom he cordially detested. He never broke with Rome; he remained a monk, and attached to the Church his whole life long. To say that he was inimical to the Church because he sharply criticised that institution would be as erroneous as to conclude that St. Paul was anti-Christian because he said some of the sharpest things about the primitive Christian churches.

Rabelais was proud of the French language, one of the very first who was proud of it, and employed it not alone to castigate his enemies, both in and out of the Church, but also to show the learned what a rich, flexible language it already had become. His long lists of words are undoubtedly, as has been suggested, written to show how rich the French language had grown to be; and that these lists are appended to subjects on which we do not now familiarly converse, we can only deplore. They probably, however, served the purpose for which they were intended, which was to show his audience that the living French language was even richer than the dead Latin, and that it could convey ideas even to a learned French audience better than the Latin could.

Rabelais was fond of the companionship of princes, nobles, churchmen, and scholars, but he had as little use for "the people" as Shakespeare had. When the man who was admitted to be the most learned of his time condescended to write in the new vivid French it must have made a profound sensation. Although the first four books of his writings are full of medical references, there are not many new medical words, but those he introduced have remained, and all of them are in active use even to this day, and with the meanings he gave to them.

Torticollis.—Rabelais hated hypocrites, and especially monastical ones, with whom he had an early, a long, and a most disagreeable experience, and he delighted to call them "wry necks." It appears the hypocritical monks often walked with the head bent and turned to one side, as an affectation of piety. Rabelais mentions these wry necks (torcoulx) as being denied entrance to the palace of Theleme, where all those free of speech and free of manner, gently educated and nimble of wit, were gathered together in a delightful community of good fellowship.[3]

Rabelais, in his description of the Ringing Island, takes another fling at the mendicant orders. On this island all the clergy were changed into birds, but the mendicant orders were changed into abhorrent birds with wry necks (le col tors), hairy paws and claws, and a belly like harpies.[5]

The first time, however, that Rabelais mentions the word torticollis (torty colli) is in that grand collection of nonsense by which the lawyer, the Lord of Suckfizzle, answers the Lord of Baiseeul in a great lawsuit, in which, with some hope of arriving at a decision, Pantagruel was called in to act as judge.[4]

By far the most interesting employment of the word, however, is in the scene in which Panurge replaces the head of Epistemon, the learned physician, which had been cut off in the battle with the giants. Panurge was very careful to adjust the head with the greatest exactitude, vein to vein, nerve to nerve, and spondyle to spondyle, so that Epistemon, on returning to life, might not find himself torty colli, as he had the most deadly hatred toward wry neck people.[5]

Excretion and Excrement.—According to Lazare Sainéan both "excretion" and "excremanz" are neologisms not found in French prior to Rabelais.[6] Rabelais relates that under the tuition of Ponocrates the young Prince Gargantua arose early, at four o'clock in the morning, and having finished his religious exercises, he "went into the secret Places to make Excretion of his natural Digestions."[7] Later, after the noonday meal, the Prince and his companions recreated themselves with games and music, and after an "Hour thus spent, and his Digestion finished, he did purge his Body of Natural Excrements; then betook himself to his principal study for three Hours or more, as well as to repeat his morning lesson, or to go on with the Book he had in hand, or also to write and draw and trace carefully the antique and Roman Letters."[8]

Quite a time after this, when Gargantua had grown to young manhood, one of his companions, Friar John, alluded to an old saying that "Matins begin with coughing and Supper with drinking." He proposed to act contrariwise and said, "Let us now begin our Matins with drinking, and in the Evening when Supper comes in, we will cough it with the best." This proposal to drink so early in the morning was a shock to Prince Gargantua, and he ventured to suggest that it was not according to the rules of medicine, and that first one "should clear the stomach of all its superfluities and Excrements."[9]

Panurge in explaining to Pantagruel, the son of Gargantua, the advantages attending on lending and borrowing, employed as an example of mutual aid, the physiological functions of the human body. He showed how the food was lent to the body, and while passing through the alimentary canal had abstracted from it what was "good and suitable," leaving behind the Excrements (which by an expulsive Faculty are voided through special conduits.[10] The word excrements is again mentioned in Book IV., Chapter LX., and in the same sense.

Excrementum and excretum were old Latin words meaning what is sifted out, the refuse; for instance chaff was called excreta tritici. Pliny uses excrementa frequently to indicate, as it does now with us, ordure, and Rabelais certainly read it there. It also applied to other matters that leave the body, as excrementum oris, spittle, and excrementum narium, mucus from the nose, which, in the old physiology, was regarded as a very important waste matter indeed.

Cerno and excerno, from which excrementum and excretum were derived, are allied, curiously enough, to both cera, wax, and stereus, dung. Discern is from the same source, and literally means that in a scene, for example, one may not at first see the

individual things, but by paying attention and looking more narrowly one "sifts them out."

The word excrements is employed by Rabelais as a synonym for Galen's superfluities, but, as Brock recently has pointed out, Galen's superfluities, perittomata, do not correspond to our expression "waste matter."[11] The conception of bodily waste in the old physiology was quite different from what it is to-day. In those days the food was seen to undergo a change both in the mouth and in the stomach, and subsequent to these changes, and in its passage along the alimentary canal, there were picked up by the blood vessels those constituents of it, spiritual and material, needed by the body. The remains, the rests, unsuitable for the body, were expelled, or as Rabelais would say, were excreted as superfluities or excrements.

The urine was supposed to be simply a fluid, an "aquosity" separated from the blood by the kidneys.[12] It was also known as a source of saltpetre;[13] it was recognized that in indigestion the urine might "burn" the urethra;[14] that a copious discharge of urine often indicated a change in the course of a disease, a crisis;[15] and it was supposed that the state of the digestive organs could often be inferred from the sediment and the flocculent floating substances in the urine.[16] Some physicians were "great for viewing the urine," while others, like Rabelais, considered it a good subject for a joke. No one regarded is as a great emunctory in any way comparable to the alvine discharges. Indeed that the alvine canal, as an emunctory, should be so insignificant is one of the surprises of physiology, and I well remember the shock it gave me when I first learned of it as a boy when studying Huxley's physiology.

Although the alvine discharges are so unimportant in physiology they still retain their place, however, in clinical medicine.

The "waste matters" of the alvine canal with us mean a trifling amount of cellulose and other insoluble food, some mucus and detritus from the walls of the alimentary canal, the waste pigment, some of the heavy mineral salts, such as iron, magnesium, lime, and phosphates, and a vast quantity of dead bacteria. As for the urine we recognize in it the nitrogenous waste chemically changed from the forms in which it entered the body, and therefore constituting different substances, and several other important organic substances and salts. And finally we know the lungs to be the great emunctory for carbon and oxygen, also chemically changed from the forms in which they entered the body.

Of the lungs as an excretor of waste, the scientific men of Rabelais' day had no more conception than we had of x-rays previous to the work of Crookes and Roentgen.

Jugular.—Jugulum and also jugulus, derivatives of jungo, I join, were names given to the bone we now call the clavicle, because it joined the shoulder to the breast. They were also terms applied to the throat; for example, it was a delicate point of honor for a vanquished gladiator to present his throat, jugulum dare, to the victor so that he might cut it, a custom which throws a charming light on public life under a militaristic government.

Jugulum was also a term applied to the hollow in the neck above the clavicles, where we now look for any back-wash in the cervical vessels from faulty action of the cardiac valves, or for fat pads in cachexia strumipriva.

The first appearance of the French word was as an adjective in the scene where the fighting monk, Friar John, rid himself of his guards. He drew his "Sword and with it smote the Archer who held him on the right, cutting clear through his Jugular Veins and the sphagatid Arteries of his neck, together with the Uvula as far as the two Glands, and withdrawing his Weapon, laid open the Spinal Marrow between the second and third Vertebræ. Upon this the Archer fell quite dead," as well he might.

It appears that the word is first encountered in Rabelais, as above, then in Canappe (1541), and then in Ambroise Paré, as the expression "vaisseaux jugulaires."[10] In English it first seems to have been employed as a designation of the jugular veins, in 1597 in a translation of Guilleaume's French Chirurgy.

Sagittal.—"Sagittale" is another neologism introduced by Rabelais, and was by him applied, as it is to-day, to the suture between the two parietal bones. This suture is so called because it meets the fronto-parietal suture at right angles, like an arrow placed upon a bow.

Caseiforme.—Paul Dorveau says that caseiforme, shaped like a cheese, is a word smithed out by Rabelais. It, of course, recalls that the brain has the color and consistency of certain kinds of soft cheese, and likewise that it has ventricular cavities like the holes in Swiss cheese. The word reappeared in the nineteenth century in chemical nomenclature in the expression precipité caseiforme, cheesy precipitate.[17] It occurs in Rabelais as an exhortation to hold in reverence the author's cheese-shaped brain, which nourishes its audience with its bubbles (of thought).

It is interesting to note the entrance of these words into the English language as given in the Oxford Dictionary: Rabelais wrote caseiforme in 1534, and it seems to have first appeared in England in 1847-9, and was then employed to designate soft, friable tuberculous material. Rabelais wrote tortycolli in 1532, and the word first appeared in English as a term for wry neck, in 1811. Rabelais employed excrement and excretion in 1532, and in English excretion was first mentioned in 1605, and excrement in 1576, and then in conjunction with superfluities, just as in Rabelais.

In English there is another word excrement, derived from excrescere, to grow out, and is a term applied to the hair and nails, for example. Shakespeare employed it, and it used to bother me mightily in reading Hamlet, where it occurs as "like life in excrements." I used to form all sorts of theories in regard to it, the most plausible being that it referred to mold growing on manure. It simply meant, as one may learn in Furness' Hamlet, that life as they understood it in Shakespeare's day manifested itself in the frightened gentleman's hair.[18]

As before mentioned jugular appeared in English in 1597.

Sagittal appeared in English in 1541, but it was not till 1547 that it appeared in the very sense in which Rabelais employed it.

A CONVENIENT METHOD FOR CONCENTRATING AND ISOLATING TUBERCLE BACILLI.

By HENRY J. GOECKEL, Phm.D.

CRANFORD, N. J.

DIRECTOR OF THE PATHOLOGICAL AND CLINICAL LABORATORY MUHLENBERG HOSPITAL, PLAINFIELD, N. J.

THE value of the antiformin method for the detection of tubercle bacilli in sputum has led me to seek a ready means of accomplishing the same result by employing a reagent in use in most hospital laboratories and in physicians' offices. By this means I eliminate a reagent likely to deteriorate and useful for one purpose only and increase the value of one in constant use.

The antiformin being essentially a solution of sodium hydroxide and sodium hypochlorite, I employ in its stead a hypobromite solution, using Rice's Bromine and Alkali Reagent* for preparing the hypobromite used in determining the urea content of urine.

I have not only employed it successfully on sputum, but likewise on tuberculous glands and in one instance on small mesenteric tubercles disclosed incidentally during a hysterectomy.

Technique.—To the sputum, caseous pus, or moderately cut or minced tissues add a few cubic centimeters (mils) of the sodium hydroxide solution (Rice's Solution No. 2). Mix well and add Rice's Bromine Solution (No. 1) in successive small portions until a clear liquid is obtained. The use of heat is not necessary.

The liquid is then diluted with distilled water to reduce the specific gravity and is centrifuged at high speed to precipitate the bacilli. These are then washed with two successive portions of distilled water, centrifuging to remove the alkali.

The residue is mounted on a microscopic slide in the usual manner, using a trace of albumin† to fix on the slide.

I have employed the method on two specimens of sputum which were exceptionally rich in tubercle bacilli and obtained quite a residue of tubercle bacilli, which were readily desiccated.

This was done to see if a liberal supply of bacilli can be obtained in this manner, with the thought that it may prove a ready means of securing the bacilli to prepare a polyvalent bacillary antigen for the tuberculosis complement fixation test. If this proves feasible it will do away with the need of growing cultures of tubercle bacilli and will simplify the production of such antigens.

To date I have not had sufficient sputa rich in bacilli to proceed with preparing and trying such antigens.

*Rice's Solution No. 1:Bromine (pure), 1 oz. (30 gm.); sodium bromide, 1 oz. (30 gm.); distilled water, q.s. ad. 8 f. oz. (250 cc.) Rice's Solution No. 2: Sodium hydroxide, 2½ oz. (70 gm.); distilled water, q.s. ad. 8 f. oz. (250 cc.).

†Albumin solution (stock): Equal volumes of egg albumin, glycerin and water, sufficient phenol to give 1 in 200; mix and filter.

191 N. Lehigh Avenue, Cranford, N. J.

Medicolegal Notes.

Dying Declarations.—In a prosecution for homicide the South Carolina Supreme Court holds that the testimony of a physician who attended the deceased after he received his mortal wound, that the deceased knew and realized that he could not live, was not inadmissible on the ground that it was a mere opinion upon the material question as to the admissibility of the deceased's statement as a dying declaration. The fact that the physician told the deceased that if he had any statement concerning anything he wanted to come out in his case, to make it to him, did not render inadmissible the deceased's statements. The physician's testimony that he told the deceased he could not live, that the deceased stated he realized that fact, and that it was hard to die, was competent to show that the deceased was "in extremis."—State v. Burton (S. Car.), 98 S. E. 856.

Expert Evidence as to Testamentary Capacity—Rule in Massachusetts.—In Massachusetts only the witnesses to the will, the testator's family physician, and experts of skill and experience in the knowledge and treatment of mental diseases are competent to give their opinions of the testator's mental condition. In that state the mere fact that a witness is a physician or a surgeon does not of itself qualify him as an expert in mental disease. It requires special skill and experience in the knowledge and treatment of such diseases to make a physician or surgeon competent to give his opinion on the subject. Whether a witness has sufficient knowledge, learning, and experience to state his opinion must be left largely to the discretion of the presiding judge. In a will contest it appeared that the testator was shot on the evening of September 20, 1916. He was taken to the hospital, where he arrived about 10.45 that night, and died about 5 o'clock in the morning following.

The surgeon who attended this man and who testified that his practice had been confined to surgery from the time of his graduation, and who had not attempted to treat any cases of mental disease, gave his evidence that the testator died of surgical shock; and that surgical shock causes anemia,, mental apathy, torpor, and dulled senses. He was not allowed to give his opinion of the testator's soundness of mind from the time he was shot until the time of his death. The Massachusetts Supreme Court held that it could not say that such refusal constituted reversible error.—Old Colony Trust Co. v. Di Cola (Mass.), 123 N. E. 454.

THE LOUSE AND TYPHUS.

THE louse has been convicted on incontrovertible evidence of being the carrier of typhus fever, and consequently the most effective means of preventing the spread of the disease is the elimination of the louse. American medical men can claim a large share in the discovery that typhus is almost entirely a louse-borne infection, but all members of the medical profession who were in Serbia during the war, and when typhus was raging from one end of that devastated country to the other, can add confirmatory and even clinching testimony that such is the case.

Of the British medical profession who worked in Serbia during the war, probably none were there so long or had so varied experiences as Mr. James Berry, chief surgeon of the Royal Free Hospital, London, and Dr. F. May Dickinson Berry. Their experiences are given in a fascinating book entitled: "The Story of a Red Cross Unit in Serbia." In the book Mr. Berry devotes a chapter to typhus and how he and his colleagues dealt with it. Extreme cleanliness was the keynote of treatment and their chief efforts were directed to getting rid of the louse. Not only were incoming patients thoroughly cleansed, but it was found necessary to shave every hair from all parts of the body. As an additional precaution petroleum was also employed for the destruction of any stray louse which might possibly have escaped attention. But very little reliance was placed upon the employment of this method when the more efficacious mechanical cleansing could be effected. The results of this meticulous cleanliness were most satisfactory. Again and again did typhus break out in the hospitals of the unit, among the newly admitted. But, with one exception, no case occurred among those who had been in a hospital for a period of two weeks, that is, long enough to have passed the period of incubation. In other words, no patient with typhus was able to transmit it to any patient in an adjoining bed, or to any person in attendance. These seem to be negative proofs of a positive character that the chief factor in the conveyance of typhus is the louse.

One extremely interesting point raised by the writer is the low mortality of typhus fever when the patients are treated under proper hygienic conditions and completely freed from all lice at the earliest possible moment. This contrasts strongly with the terribly high mortality which occurs when the patients are left in overcrowded and verminous surroundings, as was often the case in Serbia. This, as Berry says, raises the question whether the virus of typhus fever may not be to a certain extent cumulative. In any event, it may be reiterated with confidence that it was the thorough removal of all lice and nits from the patients that prevented the spread of the disease in the hospitals of the Royal Free Hospital Red Cross Unit and saved them from becoming the terrible pest houses that existed elsewhere in Serbia, where similar measures of cleanliness could not be, or were not, carried out. Mr. Berry and his coworkers claim with equal confidence that they proved that the flea does not, in Serbia at least, carry typhus. The case against the flea was never strong, but their experience appears to have demolished it altogether.

ROOM FOR THE RECENT GRADUATES.

THERE is no doubt that the country is plentifully supplied with doctors, and the young medical man who would occupy an "unoccupied field" should look outside these United States. Here he must seek consolation in the dictum: "There is always room for a *good* doctor," meaning, of course, himself. The war, which showed us a fair cross-sec- of American medicine, demonstrated the brilliant work of a few, the conspicuous scarcity of flagrant errors, the gray mediocrity of the many. In this last the recent graduate of a good medical school and hospital may perhaps find cause to congratulate himself. But his claim to the title of good doctor lies chiefly in the special training he has received. His work has been mostly medical or mostly surgical. Very few hospitals attempt to cover medicine, surgery, and all the specialties, in the brief period of the internship. And certainly the advantage of the thorough training in one subject, with a smattering of all, is more to be desired than a smattering of all with thorough training in none.

Eventually the interne is fledged, presumably with healing in his wings, but unless some older man needs an assistant, the large cities, those havens of "good" medical men, will be found very crowded, and he goes to the towns, suburban or isolated. He finds there medical men of a type altogether different from those he found in the city. He finds them versatile. In one man he beholds the obstetrician, internist, surgeon, pediatrist. Everybody does everything, or tries to, because nobody can afford to lose any sort of case. There is no division of labor, except that everybody divides his own. The young modern soon realizes that the wolf has been turned from all doors save those of professional men. He begins to spread himself. Though trained, let us say, as an internist, he does tonsillectomies, he feeds

infants, he buys a pair of obstetrical forceps. If the general medical cases don't come to him of their own accord, certainly the other fellows send him none. Perhaps the other fellows would like to specialize a bit, too, but they are all afraid to start.

It is a pity that the men in the smaller towns, especially the younger men, do not begin to take courage and limit their practices to those cases which they are best qualified to treat. Only thus can they develop any sort of team work and conserve much of the skill and effort now wasted. Only thus can the public reap the benefits of the necessarily specialized training which internes receive in our larger hospitals. Only thus can room be made for the interne when his hospital course is finished.

AMOURS OF THE AGED AND THEIR COST.

During the activities of thirty-five years of practice in a large city Dr. Armaingaud has become very familiar with a certain type of man, usually from 60 to 65 years of age but not infrequently nearly three score and ten, married and a grandfather, wealthy and recently retired from business, unusually vigorous and well preserved, intellectual and hitherto of good moral fiber, who—largely as the result of retirement from active life—begins to grow weary of home and kin and seek the company of some young woman whose age runs from 20 to 25. This type of man naturally differs from that of the lifelong libertine who does not outgrow his passions and also from that of the senile dement whose sudden bent is due to want of inhibitions and loss of moral sense. As a result of this behavior comes sexual excess and not infrequently apoplexy or sooner or later a breakdown of the health and vigor. Senility, heretofore held in check, is precipitated in full, and there is a rapid weakening of the will and mentality. The author who writes his experience in the *Journal de médecine de Paris* for September, is not a mere impressionist, for he has kept notes of 38 of these cases. The wife usually first confides the state of affairs to the physician. These cases run amazingly true to form, each one being a replica of the other. Exceptionally men continue in their original sphere of activity and the new sexual life they have assumed does not appear to wreck them, but such are not included in the series.

Of the 38 men concerned 19, or one-half, took the author's advice to renounce the mistress, while 12 were unable to break loose, and the other 7 after apparent reform relapsed into vice. The 12 who did not profit by the advice averaged 63 years of age and had an average expectation of life by the French actuary tables of 14 years. The survival was not attained by 4 years, for the average age of the men at death was 73. Only one realized his expectation and bettered it by 2 years, dying at 79. The 7 who returned to their vice averaged 65 years of age and the average survival was 13 years, but 6 died at the average age of 75, thus losing 3 years of life. The exception lived to be 80, thus beating his expectation 3 years. The 19 wise ones who took the doctor's advice should have lived on an average 12 years, as the average age was 66. Only 3 failed to attain their expectation, while the other 16 reached an average age of 86 years. Thus the author has well demonstrated a fact which is almost self-evident even to a layman.

PARAPHYSICIANS.

Under the term *paramédecin* a French writer sums up the activities of all untaught and untrained people who practise any branch of the healing art. The division between the physician and paraphysician was well known in antiquity and the Middle Ages. The latter in classical times was constituted largely by the slave practitioner and in medieval days by the barber surgeon. The word is a useful one as it carries no stigma. The author, who is Pascal in *La Presse Médicale* (October 1, 1919, xxvii, 55) also employs the synonym "medical Philistine" to designate the caste. Among paraphysicians today are masseurs, professors of physical culture, manicures and chiropodists, brace and truss fitters, makers of hygienic corsets, cosmetic specialists, spectacle fitters, herbalists, counter prescribing druggists, and even some dentists. These callings are to some extent recognized by the profession and it is only when the practitioners arrogate to themselves the right to compete with the medical man in his chosen field that we call them Philistines. From another viewpoint there is a pseudoscience for each science, so that medicine has as a foil Christian science negation, metaphysics, and the like, applied to the treatment of disease. These practitioners are also termed paraphysicians. Characteristic of all paramedicine is the short course of instruction and the quickly obtained diploma. The author quotes Professor Roger as stating that the enormous variety and number of paraphysicians is steadily lowering the prestige of the medical profession, the regular members of which in the minds of the public rank only on equal terms with the former. Both medical science and medical altruism are abased. The French physicians represent the intellect and morality of the nation as shown by the part they played in the late war. All this is quickly forgotten today and the paraphysicians are increasing at a rate previously unheard of. The educated and trained man has but one remedy, which is close organization and harmony. The Philistines are always organized and on legislative matters always present a united front.

METASTATIC PERIRENAL SUPPURATION.

That any suppurative focus, even an ordinary boil, can give rise to abscess about the kidney is not entirely a new discovery. According to a recent Paris thesis by Cleisz reviewed in *Le Progrès Médical* (Sept. 20, 1919, xlvii, 38) the general principle was known to those famous old clinicians Trousseau and Rayer, whose extensive knowledge of the subject leaves little to add. It is not to be inferred, of course, that they possessed a modern knowledge of

the pathogeny. Shortly after the discovery of the staphylococcus as the cause of osteomyelitis of the infectious type metastases about the kidney were traced to its action. A few years later Albarran proved in animal experiment that previous concussion over the lumbar region in rabbits determined the perirenal location of a metastasis of staphylococci injected into the auricular vein. It was learned later that a small focus of pus superficially situated could lead to these metastases. The author reports six cases of perirenal suppuration, not one of which was cryptogenic. A close search was necessary to throw light on the cases which had begun insidiously and had pursued a slow course before recognition; but invariably the focus was found in the shape of a furuncle or felon. When the diagnosis has been determined free access to the cavity must be obtained even if a rib resection is involved. Of the six patients all recovered in three weeks.

New Tests for Death.

Icard of Marseilles who appears to have done more work in the direction of signs of death than any of his forensic colleagues has come out with further evidence as set forth in the *Revue de pathologie comparée* for July. This is the acid reaction of the secretions after death which he has discussed in part on prior occasions. The principle does not of course, hold for the three normally acid secretions, such as the gastric juice, sweat, and urine, but applies to all other body fluids, which are normally alkaline. In three-quarters of an hour after death the "alkaline" humors will give the acid reaction. Heretofore ordinary test paper was applied to "borings" but recently the author makes use of a cutireaction obtained by forcipressure. The compression of the forceps on a fold of skin will when properly applied force the serum into an artificial cul-de-sac to such effect that a little serosity will escape, whereupon it is tested with ordinary test paper and after 5 or 10 minutes' delay the reaction, if death has occurred, will be acid, while if the subject still survives it will be alkaline. The borings formerly used were obtained by plunging a cannula into the liver and withdrawing it. This and similar procedures are sometimes repugnant to the relatives of the deceased, but use of the forceps is not so likely to be antagonized.

News of the Week.

Sickness and Mortality Figures.—The report of The New York State Commissioner of Health, made public November 17, shows a marked increase in the birth rate for September, and a death rate which is lower than the record low rates of July and August. The birth rate increased from 18.8 per thousand in August to 21.3 in September. Deaths decreased from 10.4 in August to 10.3 in September. The infant mortality fell from 97, in August, to 81, in September, per thousand living births. The highest mortality from typhoid fever for the year was 57 in September, the mortality for the corresponding month in 1918 being 78. Measles and whooping coughs showed decreases over the several preceding months, while scarlet fever and diptheria showed slight increases in the number of deaths. Influenza showed a slight increase over the preceding month, while the pneumonias continued to show decreases below the average of the same months of the preceding five years. The number of deaths from accidents was less in September of this year than in the same month in 1918, the most notable decrease being in automobile accidents, which fell from 155 in August to 79 in September.

Trachoma Hospital for Florida.—The Florida State Board of Health, at its meeting of November 6, appropriated $6,000 for the establishment of a trachoma hospital. It was proposed to institute a comprehensive program of clinical work and a general campaign of education against this grave health problem. The United States Public Health Service agreed to supplement this appropriation, and to establish the hospital provided a building and maintenance funds are supplied by local and State health boards.

Birth Control Case Dismissed.—The appeal of Margaret Sanger on the constitutionality of the New York Birth Control Act was dismissed by the Supreme Court in Washington, November 17, without an opinion, for lack of jurisdiction. Mrs. Sanger was sentenced to thirty days' imprisonment for conducting a "birth control clinic" in Brooklyn.

Subscription Funds for St. Louis College of Physicians and Surgeons.—At its second annual meeting, November 6, the Alumni Association of the St. Louis College of Physicians and Surgeons pledged itself to raise a fund of $50,000 for the improvement of the college facilities.

Boylston Medical Prize for 1919.—These prizes, which are open to public competition, are offered for the best dissertation on questions in medical science proposed by the Boylston Medical Committee. For this year there is offered a prize of three hundred dollars and the Boylston Prize Medal, for the best dissertation on the results of original research in medicine, the subject to be chosen by the writer. The Boylston Prize Medal will be added to the money prize only in case the winning essay shows special originality in the investigations detailed. Dissertations entered for this prize must be in the hands of the Secretary, H. C. Ernst, M. D., Harvard Medical School, Boston, Mass., on or before December 31, 1919. Each dissertation must bear, in place of the author's name, some sentence or device, and must be accompanied by a sealed packet bearing the same sentence or device and containing the author's name and residence. Dissertations must be printed or typewritten, and their pages must be bound in book form.

Samuel D. Gross Prize.—The conditions of this contest are that the prize "shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, oratorio, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations, the candidates for the prize to be American citizens."

It is expressly stipulated that the competitor who receives the prize shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the

Philadelphia Academy of Surgery, and that on the title page it shall be stated that to the essay was awarded the Samuel D. Gross Prize of the Philadelphia Academy of Surgery. The essays, which must be written by a single author in the English language, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 19 S. 22d St., Philadelphia, on or before January 1, 1920. Each essay must be typewritten, distinguished by a motto, and accompanied by a sealed envelope bearing the same motto containing the name and address of the writer. The prize is fifteen hundred dollars.

Charitable Bequests.—The will of Louis J. Weil, of New York City, who died August 31, bequeaths $5,000 to Mt. Sinai Hospital to found a bed in memory of his father; $1,000 each to the Children's Aid Society and the Hebrew Benevolent Society, and $500 each to the Montefiore Home for Chronic Invalids and the Home for Aged and Infirm Hebrews.

The will of Mrs. Mary J. Kingsland, of New York, makes bequests of $50,000 to the New York Society for Ruptured and Crippled and the Nursery and Child's Hospital. The Association for Improving the Condition of the Poor, the Charity Organization Society, St. Luke's Hospital and the Tarrytown Hospital each receive $25,000.

Medical Society Elections.—The Northern Berkshire Medical Association, at its annual meeting in North Adams, Mass., September 21, elected the following officers for the ensuing year: *President,* Dr. George L. Curran; *Secretary,* Dr. George H. Thompson; *Treasurer,* Dr. F. W. Montgomery.

The Kentucky Medical Association, at its sixty-ninth annual meeting held in Ashland, September 25, 1919, elected the following officers for the ensuing year: *President,* Dr. J. G. South, Frankfort; *President-Elect,* Dr. W. W. Anderson, Newport; *Vice-Presidents,* Dr. Irwin Lindenberger, Louisville; Dr. C. P. Layne, Ashland, and Dr. D. J. Travis, Eddyville; *Secretary-Treasurer,* Dr. Arthur T. McCormack.

The Waldo County Medical Association, at its annual meeting held in Bangor, Me., Oct. 17, 1919, elected the following officers for the ensuing year: *President,* Dr. Eugene L. Stevens, Belfast; *Vice-President,* Dr. N. R. Wool Cook, Unity; *Secretary and Treasurer,* Dr. Carl H. Stevens, Belfast.

The Grafton County, (N. H.) Medical Society, at its sixteenth annual meeting held Oct. 16, 1919, elected the following officers for the ensuing year: *President,* Dr. Samuel Fraser, Wentworth; *Vice-President,* Dr. F. C. Russell, Haverhill; *Secretary-Treasurer,* Dr. J. M. Wise, Glencliff.

The Clinical Congress of the American College of Surgeons, at its ninth annual meeting held in New York, October 20-24, 1919, elected the following officers for the ensuing year: *President,* Dr. George E. Armstrong, Montreal; *First Vice-President,* Dr. Rudolph Matas, New Orleans; *Second Vice-President,* Dr. Howard Packard of Boston; *Regents for term expiring in* 1921: Dr. Alexander Primrose, Toronto; Dr. Albert J. Oschner, Chicago; Dr. George W. Crile, Cleveland; Dr. Harvey Cushing, Boston; Dr. George E. deSchweinitz, Philadelphia; Dr. William J. Mayo, Rochester. *Regents for the term expiring* 1922: Dr. John M. T. Finney, Baltimore; Dr. James B. Eagleson, Seattle; Dr. Charles H. Mayo, Rochester; Dr. J. Bentley Squier, New York; Dr. Walter W. Chipman, Toronto.

The Southern California Homeopathic Medical Society, at its twenty-ninth annual meeting held in Los Angeles October 8, 1919, elected the following officers for the ensuing year: *President,* Dr. A. P. Williamson, Santa Monica; *Secretary and Treasurer,* Dr. Charles S. Salisbury, Los Angeles.

The Washington County (Me.) Medical Society, at its annual meeting held in Calais, October, 11, 1919, elected the following officers for the ensuing year: *President,* Dr. J. A. Walling, Milbridge; *Vice-President,* Dr. S. L. Hunter, Machias; *Secretary-Treasurer,* Dr. H. B. Mason, Calais.

The Medical Association of the Southwest, at its annual meeting held in Oklahoma, Ok., October 8, 1919, elected the following officers for the ensuing year: *President,* Dr. Ernest Day, of Arkansas City; *First Vice-President,* Dr. Horace Reed, Oklahoma City; *Second Vice-President,* Dr. Wilse Robinson, Kansas City, Mo.; *Third Vice-President,* Dr. W. H. Deadrick, Hot Springs, Ark.; *Fourth Vice-President,* Dr. W. T. Wilson, Navasota, Tex.; *Secretary,* Dr. Fred H. Clark, El Reno.

The Vermont State Medical Society, at its one-hundred and sixth annual meeting, held in Burlington, October 10, 1919, elected the following officers for the ensuing year: *President,* Dr. M. F. Macguire, Montpelier; *Vice-President,* Dr. Alan Davidson, St. Albans; *Secretary,* Dr. William G. Ricker, St. Johnsbury; *Treasurer,* Dr. David Marvin, Essex Junction.

The Colorado State Medical Society, at its annual meeting held in Denver October 9, 1919, the following officers were elected for the ensuing year: *President,* Dr. F. R. Spencer, Boulder; *Vice-President,* Dr. W. S. Chapman, Walsenburg; *Secretary,* Dr. Crum Epler; *Treasurer,* Dr. W. H. Crisp.

The American Association of Electrotherapeutics and Radiology, at its annual meeting held in Philadelphia, Sept. 9-12, 1919, elected the following officers for the ensuing year: *President,* Dr. William Martin, Atlantic City, N. J.; *Vice-Presidents,* Dr. Virgil C. Hinney, Wellsville, N. Y.; Dr. William T. Johnson, Philadelphia, Pa.; Dr. St. John Wright, Akron, Ohio; Dr. Mary Arnold Snow, New York; Dr. John H. Burch, Syracuse, N. Y.; *Treasurer,* Dr. Emil Heuel, New York; *Secretary and Registrar,* Byron Sprague Price, New York.

Obituary Notes.—Dr. Edward L. Hottenstein died at Kutztown, Pa., on October 28, at the age of 55 years. He was graduated from Jefferson Medical College in the class of 1886.

Dr. Thomas Barker Eastman of Indianapolis, died November 10, from carcinoma, at the age of 50. Dr. Eastman was the son of Joseph Eastman, pioneer gynecologist of the Middle West. He was graduated from the Central College of Physicians and Surgeons, Indianapolis, in 1893, in which institution he held the post of professor of abdominal surgery and diseases of women for a number of years. Later he became clinical professor of gynecology in the Indiana University School of

Medicine, Indianapolis. He was gynecologist to the Indianapolis City Hospital, surgeon to the Joseph Eastman Hospital, and member of the staffs of the Methodist and Deaconess hospitals. He was a member of the American Association of Obstetricians, and in 1914 was appointed a member of the Indianapolis City Board of Health.

Dr. Junius M. Hall of Chicago died in that city October 30, at the age of 68. Dr. Hall was graduated from the College of Physicians and Surgeons, New York City, in the class of '74, and practised for a few years in the place of his birth, Northampton, Mass. In 1871, he went to Chicago, where he practised up to the time of his death. For fourteen years he served as medical inspector in Chicago.

Dr. Hiram Hunt of Greenville, Me., died at his home November 4, 1919, at the age of 59. He was a member of the class of '84 of Bowdoin Medical College.

Dr. Stewart Alfred McComber of Schenectady, N. Y., associate director of athletics at the Foyer du Soldat, died at the American Hospital at Neuilly, November 5. Before going overseas with a Y. M. C. A. contingent, in July, 1918, Dr. McComber, who was graduated from the Detroit College of Medicine, was physical director and professor of hygiene at Union College, Schenectady.

Colonel Robert Wilson of Montreal, Canada, died under an anesthetic, in the Toronto Hospital, November 6. He was prominent in military, medical, and Masonic circles, and was a pioneer in roentgenology in Canada. He served four years overseas, and after the Armistice became active in the work of physical rehabilitation of wounded soldiers.

Dr. L. L. Williams, sixty years of age, was shot and instantly killed in front of his office in Brazil, Ind., November 3. Dr. Williams, who was graduated from the Louisville Medical College in 1878, practised for several years in Jeffersonville, Ind.

Dr. Walter Peyre Porcher, an honored member of the older element of the medical profession in Charleston, S. C., died at his home in that city, November 2. Dr. Porcher was graduated from the Medical College of the State of South Carolina, in which institution he was professor of rhinology and laryngology.

Obituary.

CHARLES FREMONT TAYLOR, M.D.,

PHILADELPHIA, PA.

Dr. Charles F. Taylor, editor and publisher of *The Medical World*, died on November 4 of a cardiac disease after an illness of several months. Dr. Taylor was born July 3, 1856, in Attica, Ind., and studied at the Louisville College of Medicine and at the College of Physicians and Surgeons of Indianapolis, taking his medical degree from the latter in 1880. He practised in Indianapolis for a few years, and then removed to Philadelphia where, in 1883, almost immediately upon his arrival, he established *The Medical World*, now in its thirty-seventh volume. Dr. Taylor, in addition to his medical concerns, was deeply interested in the science of government and established a quarterly journal called *Equity*, devoted to a consideration of problems relating to the public weal. Dr. Taylor was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, the American Medical Association, the American Medical Editors' Association, the Philadelphia Club, and many art, civic, political, and ethical societies.

HENRY WEIGHTMAN STELWAGON, M.D.,

PHILADELPHIA, PA.

Dr. Henry Weightmann Stelwagon died of angina pectoris at Philadelphia on October 18, at the age of 66 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1875, and he served a term as intern in the Philadelphia General Hospital. From 1880 to 1890 he was Physician in Charge of the Philadelphia Dispensary for Skin Diseases; from 1885 to 1915, Dermatologist to the Philadelphia General Hospital and in 1916 he was made Consulting Dermatologist; from 1885 to 1890, Instructor in Dermatology in the University of Pennsylvania; from 1888 to 1907, he was professor of Dermatology in the Woman's Medical College of Pennsylvania; and from 1890 to 1918, Professor Dermatology in Jefferson Medical College. He was a member of the Philadelphia County Medical Society, of the Medical Society of Pennsylvania, of the American Medical Association, of the Philadelphia Dermatological Society, and of the American Dermatological Association, and a Fellow of the College of Physicians of Philadelphia. He was the author of a text book on Diseases of the Skin which passed through a number of editions.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, Oct 24, 1919.

War on the Rat.—Under the direction or control of the Board of Agriculture there is now being waged the greatest campaign against rats ever organized in Great Britain. The efforts for the destruction of these pestilential vermin is being taken up not only in populous centers, but in remote country villages, harbors, docks, and in fact in every place known or suspected to be rat infested. Sir James Crichton Browne ten or twelve years ago, estimated that in England alone the value of food destroyed by rats amounted to £15,000,000 a year. Since then the proportion has increased alarmingly, for while the rat population has increased enormously, the price of food has more than doubled. Indeed, it was stated last summer that the value of food destroyed by rats in the country had risen to £40,000,000 a year. It is also asserted that there are more than 40,000,000 rats in Great Britain. With regard to the rat as a menace to health, and especially as the carrier of the plague, there is no need to dilate. This aspect of the question affects Great Britain to a less degree than it affects America, but even in Great Britain it is a consideration. There is one feature of the rat situation which is of some interest, which is that

the black rat which was supposed to have been exterminated by its bigger and more aggressive brother, the brown rat, has been found in very considerable quantities in Great Britain in recent years. As for the manner in which rats can be destroyed if organized systems are set in force, attention may be drawn to the fact that the sanitary officials of the Corporation of the City of London have caught and destroyed rats at the rate of about a thousand a week during the past twenty years. At Liverpool the destruction has been even greater and has approximated to something like fourteen hundred a week. In Norfolk the work of rat destruction has been so considerable as to involve an outlay equal to a 3d. rate for the whole county.

Medical Society of London.—The week beginning October 12 was remarkable for the number of important medical meetings which were held in London. On Monday evening, Oct. 13, the Medical Society of London had its first annual meeting of the year 1919. A president was elected. Mr. V. Warren Low, whose presidential address was concerned with the advances which had been made in surgery during the war, predicted that much of the time of medical societies would be occupied for some years to come in digesting the war experiences and in judging how far they applied to conditions of peace. Dr. F. de Haviland Hall read a paper on angina pectoris with low blood pressure. He said in part, that since the time when Lauder Brunton, in 1867, found that anginal pain in a patient with aortic regurgitation was relieved by the inhalation of nitrite of amyl, drugs having a vasodilator action had been much employed in cases of angina pectoris. The view that the immediate exciting cause of a paroxysm was a sudden rise in the tension in the sytemic arteries justified this form of treatment. It had been more or less assumed in the past that high blood pressure was an invariable concomitant of angina pectoris, but in recent years attention had been directed to the occurrence of typical anginal attacks in the presence of a low blood pressure. As he had not had the opportunity of taking the blood pressure at the time of attack he could not state confidently that a high blood pressure was not present, but in his experience the victim of angina pectoris had usually a blood pressure considerably above normal, and it was to an intensification of the already high pressure that an anginal attack was commonly due. However, in this paper he was drawing attention to those exceptional cases in which anginal symptoms occurred in patients who had in the intervals a systolic blood pressure about or below normal. He had been impressed by the failure of vasomotor dilators to give relief in these cases, and they might even prove dangerous if admimistered incautiously. The prognosis, always grave in angina pectoris, was considerably worse when anginal symptoms occurred in patients with a low blood pressure. As a general rule angina pectoris occurring in patients with a low blood pressure required to be treated on different lines from those in which the angina was associated with high tension. Nitrites and other drugs promoting vasomotor relaxation might be worse than useless. In cases in which pain was the chief symptom the only drug of any value was morphine in combination with atropine given subcutaneously. In the intervals the patient should be carefully dieted, the amount of alcohol should be limited and tobacco forbidden. Excess in tea and coffee should be checked. Among cardiac tonics no drug was so generally useful as arsenic; it might be combined with iron if the patient were anemic. The addition of strychnine would help to improve the tone of the patient.

The Society for the Study of Inebriety.—This society held a conference and an extremely busy day in London on Tuesday, Oct. 14. The morning and afternoon sessions were held in the rooms of the Medical Society of London. The piéce de resistance, the Norman Kerr Lecture, was given by Dr. Mary Scharleb. The subject was "The Relation of Alcohol and Alcoholism to Maternity and Child Welfare." At the morning session the president of the society, Sir Alfred Pearce Gould, delivered an introductory address. Lord D'Abernon read a paper on "The Scientific Basis of Drink Control." According to Lord D'Abernon there were three main ends to be sought in any system of liquor control. These were: (1) Avoidance of the continuous drinking of alcoholic liquors, which is apt to occur with uninterrupted drinking hours. (2) Discouragement of the use of beverages of excessive alcoholic strength. (3) Avoidance of drinking on an empty stomach. Indicating the three points set out above as the three main objects to be achieved by liquor control the speaker said the governing principle of physiological control should be discontinuity of drinking hours and dilution of alcohol. The lesson of war time restrictions on the liquor traffic was that the question "how the nation drinks" is even more important than the question "how much the nation drinks." Regulate on sound physiological lines the modes and times and circumstances of drinking and within reasonable limits, the amount of consumption might with confidence be left to the operation of ordinary economic forces. This was a conclusion which should be full of encouragement for those who believed that the use of alcohol could be regulated. For it was quite evident that the intelligent regulation of the conditions of drinking, though it might require more knowledge, more thought, and more study than a simple limitation of the amount drunk, would be less unpopular and would have many practical advantages. Unless recourse was had to rationing, to which there were obvious objections, a policy of restricting the supply of alcoholic beverages must give rise to rush drinking, and to inequality of distribution, and would almost inevitably open the door to cornering and to the operations of the profiteer. It tended to combine the maximum of invitation to the public and the maximum loss to the revenue with the minimum of benefit to real temperance. On the other hand, if by the method of regulation on physiological principles they could secure adequate results for the health and sobriety of the nation those results would be obtained with less apparatus, with less risk of creating alternative evils, with less disturbance to trade, and less

abrupt violation of the habits of the community. Further, the means by which these ends might be achieved were compatible with and would be even aided by appropriate taxation, which should go a long way to reestablish national finance, either by relieving it of the cost of war pensions, or in one way or another paying off a large proportion of the indebtedness due to the war. According to the hard and fast advocates of prohibition, "scientific" restriction, however scientifically planned, is still mere restriction. To abandon the quest of temperance reform at that point, to plead that we have done, with the aid of science, the best we can along the line of least resistance, this surely is not evidence of the spirit which is to make a new Britain. There are those who think that "half a loaf is better than none" and that the surest way to introduce temperance into Great Britain is by gradual means. Dr. Mary Scharlieb at the evening session, in a lengthy paper, covered the entire ground of the question of alcoholism in its relation to social problems. Indeed, she did not dwell especially upon that phase of the matter referred to in the title of her paper. She said, in part, that from the evidence of those who had first-hand information, it was seen that the sobriety of women and girls industrially employed during the war was remarkable. Accidents in factories were seldom or never found to be due to the influence of drink on women or girl workers. Even in certain forms of very hard and very trying work where the employees were chiefly women and girls of the roughest class, there was not much drinking.

Seventh Annual Conference of the National Association for the Prevention of Tuberculosis.— This very important conference took place in the Central Hall, Westminster, on Oct. 16 and 18. The chairman for the first day was Lord Glenconner, Honorary Treasurer, National Association for the Prevention of Tuberculosis. At the morning session Dr. Christopher Addison, Minister of Health, gave the opening address. He said in part, that the war had added a great number of men to the ranks of sufferers from tuberculosis. He was sorry to say that in consequence of the necessary suspension of many activites in Great Britain, with the absence of many skilled men from the tuberculosis service in the ranks of the Army Medical Corps, and the entrance of a large number of women into industrial service, there had been an increase of tuberculosis in some directions, notably among women. In respect of preventive measures he laid most stress upon improved housing. By the end of the month it was hoped under the terms of the act to receive from the different authorities a program of operation, which he realized would take time to carry out, in connection with housing and to that program the Ministry looked to include the gradual provision of alternative accommodation which would lead to the clearing away or reconstruction in slum areas. He emphasized the point that unless the housing program had as an ingredient of it the cleaning of insanitary buildings or rendering them sanitary, the Ministry would not be able to cope with the problem of tuberculosis or of many other diseases. It has been pointed out repeatedly in these letters the crux of the health problem in Great Britain lies in the ability of the new Ministry of Health to effect a revolution in the housing situation. It is an immensely difficult problem to solve and steps towards its solution are proceeding slowly. Almost all the speakers at the conference insisted that bad environment is at the root of tuberculosis and that the only hope of overcoming the disease is by the provision of sanitary houses in adequate numbers. The scope of the program of the Conference was as follows: The completion of tuberculosis schemes throughout the country, in relation to: (1) The Ministry of Health. (2) Local Authorities and Insurance Committees. (3) Pension Boards and Committees, Discharged Soldiers and Sailors. (4) General Practitioners. (5) Red Cross and Other Voluntary Activities. (6) Training of Doctors and Nurses. (7) Training of Voluntary Workers.

2. Sodium Citrate in the Treatment of Pneumonia.— W. H. Weaver, impelled by his success in twenty-four cases reported in 1912 and thirty-five additional cases reported in 1918, made further investigations in the treatment of pneumonia by the administration of full doses of sodium citrate, in order to establish a scientific basis for its action. The history of its first application is given, and the pathology of lobular or bronchopneumonia and lobar pneumonia is given. There is in each condition the same urgent necessity for the restoration of the cardiopulmonary circulation, which is conceded to be the chief indication in pneumonia. Restoration of the cardiopulmonary circulation is largely a problem in mechanics or hemodynamics. The volume of the flow depends upon three elementary conditions. First, blood pressure; second, fluidity of the blood or viscosity; third, size and length of the bloodvessels. The degree of viscosity of the various liquids has been measured by instruments of precision, and is based on the viscosity of water as the unit, and stated as the coefficient of viscosity. Mathematically considered, the volume of the flow varies inversely as the coefficient of the viscosity, other factors remaining the same; that is, pressure, and length and diameter of tube or capillary. The coefficient of human blood has been found by various observers to be "about five times that of water." Hence, the blood pressure remaining the same, one-fifth as much blood as water would flow, and, if the viscosity of the blood is reduced more nearly to that of water, it will necessarily flow that much more freely. Conversely, if viscosity is increased, the flow is reduced. Carbon dioxide, ether, and chloral have been found to increase viscosity. Opitz demonstrated that the infusion of large quantities of normal saline solution, and of distilled water, reduces viscosity; also, that viscosity reacts sharply to heat and cold. Warm water baths decreased viscosity very considerably, while cold water had the opposite effect. Loss of water which the body suffers from any cause, such as drinking an insufficient amount of water, dry hot air, and high temperature, increases the viscosity of the blood, rendering recovery more difficult. Other factors remaining constant, the magnitude of the flow must become greater the less the viscous resistance. Regarding the relationship existing between viscosity and coagluability, it

should be stated that viscosity is due to internal or molecular friction. As this molecular friction increases, the fluid becomes gradually less fluid, approaching and finally becoming thick, semisolid, then solid. This may be brought about by heat or cold, or by some chemical change in the molecular constitution of the substance. Reliable observations (Lee and Dochez) seem to show that the coagulation time of the blood in pneumonia is delayed. This delay in the coagulation time and the resultant reduction of viscosity makes it easier for the blood to find its way through the obstructed bloodvessels of the lung. During the hepetization of the affected lobe, there is a deposit of a considerable portion of the fibrin forming elements of the blood and prolonged coagulation and increased fluidity would be the natural result. High viscosity and coagulability at this time would certainly not conduce to restoration of the cardiopulmonary circulation and recovery. The action of the sodium on coagulation has been studied by a number of observers. The peculiar property of sodium citrate in preventing coagulation and reducing viscosity of the blood is recognized and in use today as a scientific fact, and should need no further proof. While alkaline salts are necessary, these salts are rapidly eliminated and are not replaced from the restricted diet upon which most fever patients place themselves by loss of appetite and other causes. The degree of alkalinity of normal blood expressed in terms of sodium hydrate is equivalent to from 182 to 275 milligrams to 100 c.c. of blood, so that a wide variation is not incompatible with health. It has been maintained that a medium degree of alkalinity of the blood is necessary in order that it may exert its normal antitoxic power, and that leucocytes increase in numbers in proportion as the alkalinity of the blood becomes more marked. It has also been observed that immuntiy to infection increases with the increased alkalinity of the blood and diminished when the alkalinity was reduced. Hence, with increased alkalinity of the blood must come increased antitoxic power, an active leucocytosis, and its greatest possible fluidity, all of which are necessary in order to meet the chief pathogenic indication in pneumonia. In order to meet the indications as outlined, Weaver gives sodium citrate in large doses with plenty of water at the rate of fifteen to twenty grains an hour, or forty grains every two hours, sometimes more, to a full sized adult, continued night and day until the result is attained. Occasionally, this dose will act as a purge, and the salt passes off through the bowels. This should be checked by a few doses of an opiate. The medicine should be continued into the second or third day, after the crisis, to assure complete resolution. It should be firmly insisted upon that small doses have no effect and will be disappointing. It is understood that citrates are converted into carbonates in the blood in the ordinary doses in which they are given; but with the larger doses, certainly some of it may go over into the blood as citrate, and when the point of saturation of the calcium is reached, the blood will not coagulate so readily and is of the highest possible fluidity; then it begins to find its way through the pervious but collapsed bloodvessels of the hepetized lobe. If the blood pressure is low from cardiac disease, old age or other causes, and the pulse rapid, digitalis and strychnine should not be forgotten. In the recent pandemic of influenza the writer found that in the lobar form of influenzal pneumonia sodium citrate would reduce the temperature when other measures failed; but the consolidated lobe cleared up only after the lapse of from one to three weeks. In all the cases of lobar pneumonia of influenzal origin the patients treated with sodium citrate recovered, but not by crisis, as in the noninfluenzal pneumania concerning which this paper was written.

6. Camphorated Oil Tumors.—W. H. Mook and W. G. Wander state that they have been observing in increasing numbers tumors that have resulted from the injection of camphorated oil, among patients in the Barnard Free Skin and Cancer Hospital, at the Washington University Clinic, and in their private practice. They have heard of other cases, and in view of the great quantities of camphorated oil injected during the epidemic of influenza last year as well as its common use in operating rooms, as a stimulant, feel that a word of warning may not be amiss. The tumors due to the subcutaneous injection of camphorated oil greatly resemble the paraffinomas in their slow development, their peculiar concrete-like type of infiltration, and the time in which they develop after injection. Their location, however, is so totally different from that of paraffinomas as not even to cause suspicion that they are of the same nature, and due to the same cause, namely, the subcutaneous injection of oil, probably mineral. An analysis of the cases shows a series of six patients who developed tumors in the arms, some also in the thighs, all with practically the same history and lesions of the same character. The size of the tumor depends on the amount of oil injected, and, instead of being rounded in outline they are linear, with definite sharp angles marking them off from the normal connective muscular tissue, in which they are located. The microscopic sections demonstrate the encapsulated oil cavities. It is apparent that liquid petrolatum may remain as an inert foreign body in tissue. The writers have reached the conclusion that it is dangerous to use liquid petrolatum as a vehicle for any remedy to be injected in subcutaneous tissue. This fact has been well established with reference to paraffin injections, and the tumors resulting from the injection of camphorated oil made with liquid petrolatum strengthens the conclusion.

8. Arsphenamin in Pneumonia with Delayed Resolution in Syphilitic Soldiers.—George Douglas Head and John L. Seabloom recall the fact that in some individuals an acute disease will so derange the protective mechanism of the body that an old infection lying apparently dormant will be reactivated thereby. The reactivation of malaria and tuberculosis in pneumonia have been noted. The writers, however, are not aware that the attention of the profession has been called to the fact that syphilis may act to prolong or delay the reparative process in the lungs of persons who have had pneumonia, and that syphilitic persons with pneumonia are liable to exhibit signs of delayed resolutions for weeks or months at a time. The healing process in such individuals does not progress as in the normal individual, and the usual methods of treatment are of no value. They cite several cases observed at Camp Wheeler during the winter, 1918-1919, which illustrate the effect of syphilis in causing delayed resolution and the prompt effect of arsephenamin in clearing it up, and recommend its use in cases of unresolved pneumonia in syphilitic patients.

6. Trench Fever and War Nephritis. J. H. Lloyd.
7. The French Medical Curriculum; A Contrast. D. T. Barry.

4. Some Causes of Failure in the Vaccine Treatment of Arthritis, Rheumatism, and Neuritis.—H. Warren Crowe groups the causes of failure of vaccine treatment in these diseases under six heads: (1) False diagnosis; (2) errors in bacteriology; (3) incorrect or inefficient vaccine; (4) faulty administration of vaccine in regard to dosage and interval; (5) peculiarities in the constitution of the patient and in his response to vaccines; (6) mistakes in general treatment. To false diagnosis may be added the failure to discriminate between curable and incurable conditions. In the main fibrosities and muscular rheumatism are easy to recognize, and can be readily and successfully treated by vaccines. The diagnosis of arthritis is much more difficult. The monarticular varieties are best left alone, especially if of long standing. Failure here is the rule rather than the exception. Where multiple joints are involved the essential thing from the vaccine point of view (aside from the bacteriology) is to decide whether the condition is one of chronic rheumatoid arthritis in its generally accepted sense or one of rheumatism. The earliest, almost pathognomic, sign of the former is creaking of the occipitao-atlantoid joint, *x*-rays should always be employed before attempting the treatment of any chronic joint trouble, for there can be no complete success where bony changes have taken place. It is very important to distinguish between rheumatic fever and acute febrile rheumatoid arthritis. The former will, as a rule, yield readily to vaccines, whereas the latter is not only extremely intractable, but will often flare up most alarmingly after a minimal dose. Full doses of salicykates should decide the point. Mistakes in bacteriology are extremely difficult to avoid. It is so fatally easy to find a microbe either in the gums, from the nose, from the feces or in the urine, and serum reactions give but little assistance in determining pathogenicity. For these reasons clinical diagnosis is of paramount importance, and given correct diagnosis, stock vaccines are usually much more efficient in this group of diseases than autogenous. In discussing incorrect or inefficient vaccines, the writer attributes this source of failure as partly due to faults in clinical diagnosis and partly to bacteriological errors. It is far wiser to use a well-tried stock vaccine than to prepare one from an organism of doubtful etiological significance. While it is almost impossible to give any scale of dosage that will apply to more than a very few cases. This difficulty can be largely surmounted by charting the daily weight of the patient under comparable conditions of time and clothing. Symptomatic reactions read in relation to the daily weight chart will be found to provide an excellent guide. In all cases of sentitiveness the weight chart will be found to be an almost indispensable guide. One of the mistakes in general treatment is that of ordering for patients suffering from rheumatoid arthritis haphazard massage or telling him "to walk it off." When vaccines are being given such directions are most dangerous on account of the autoinoculations induced. It is important to guard against the fallacy that because the vaccine of a given organism has a pronounced effect on the patient that therefore this organism must be the causal germ of the disease. Sir Almroth Eright has recently suggested that vaccines are not nearly so specific as has been thought. His conclusions strengthen the case for a more extended use of stock vaccines.

5. Diurnal Variation in Body-Weight in Tuberculous Patients.—J. MacNaught Scott records observations made on the body-weight of patients attending Stepney Green Tuberculosis Dispensary during the time he was acting medical officer. The patients were weighed at each attendance between 2 and 4 in the afternoon and the following morning at 10 a. m. It was noticed that in the majority of cases there was a fall in the morning weight as compared with the previous afternoon. It varied from ½ pound to as much as 4 pounds. Out of a total of 962 recorded weights, 146 showed no variation, 205 showed an increase, and 611 showed a decrease. The average increase was 0.77 and the average decrease 1.03 pounds. From the detailed figures the writer concludes that a tuberculous patient will record a greater fall in weight in the morning, as compared with the afternoon weight, than a person who is merely a suspect. Also that where an increase is recorded in a positive case that increase is likely to be less than an increase in a suspect case. The more serious and advanced the case the greater the variation in weight recorded. The decrease is greatest between the ages of 20 and 24 years of age, and is proportional to the severity of the infection.

8. Notes on a Case of Poisoning by Hydroquinone. Alexander Mitchell and John Webster.

2. Tranquil Tracheotomy by Injecting Cocaine within the Windpipe.—Sir St. Clair Thomson describes his method of injecting cocaine into the windpipe preceding tracheotomy whereby the commotion usually accompanying the opening of the trachea may be avoided. His method of procedure is as follows: An ordinary hypodermic syringe is charged with about 2½ per cent. solution of cocaine. As soon as the tracheal rings are laid bare the syringe is grasped with the forefinger about one inch from the extremity of the needle, and with this the windpipe is sharply stabbed between the tracheal rings. The middle, ring, and little fingers are rested on the neck and they prevent the point from penetrating more than a quarter to half an inch within the lumen of the trachea. The cocaine solution is injected into the cavity of the windpipe, some five to fifteen drops, and the needle is sharply withdrawn. The liquid in the windpipe at once gives rise to a slight stuffy cough. It causes no spasm or distress and as it trickles down toward the region which the endoscopists know as the sensitive spot of this area—namely, the carina at the bifurcation of the trachea—this tickling cough soon ceases. If there is no great urgency, ten minutes should be allowed to elapse, the time being occupied in clearing the front of the trachea, checking any bleeding, preparing the tube, etc. At the end of that time the incision can be made into the trachea and the cannula introduced without pain, spasm, or even the slightest cough, as quietly and smoothly as the original incision into the skin. The 2½ per cent. strength is as effective as the 5 per cent., and in children 1 per cent. solution and five drops will prove sufficient. During the past five years the writer has used this procedure scores of times, as have also his associates in King's College Hospital, with uniformly good results. Though he has not used it in children under four years of age, he thinks it could be safely employed in young children.

6. A Preliminary Note on the Treatment of Inoperable Cancer with Selenium.—E. Watson-Williams reviews previous reports on the use of selenium in cancer and reports his observations on 24 cases treated by this agent. Selenium as available for injection, he says, is a protected colloidal suspension of srethroselenium beta, prepared chemically or electrically, and is a dichroic coral red fluid. It appears not to be very stable. It is isotonized, if this has not already been done before injection, by the addition of sodium chloride solution. The dose employed represents 0.0005 or 0.003 gram of the metal, preferably administered intravenously. Intramuscularly it is painless, and this may prove the method of choice in ambulatory cases, as it is probably more uniformly absorbed. A transient general reaction occurs with the earlier injections.

The beneficial results observed in greater or less degree included: Diminution or disappearance of pain, this being the earliest and most striking result; diminution in tenderness; healing of ulcerated surfaces; diminution in the size of the tumor and secondary deposits; increased mobility, improvement in anemia and cachexia; improved sleep, and improved memory and general health. The improvement has been most marked in carcinoma of the alimentary tract. In carcinoma of the larynx it seems advisable to proceed cautiously so that the treatment may be modified or suspended in the event of a considerable focal reaction.

1. Some General Principles of Therapeutics.—Robert Hutchison emphasizes as the first principle of therapeutics the necessity of having a plan of treatment, which must be founded on what are called the indications for treatment. Having formed a plan of treatment, the next thing to remember is the importance of not lightly making changes in it; having laid down the course clearly, one must not be diverted into side issues by the desires of the patient or his friends. The next thing about the plan is that it should, if possible, be a simple one. Just as planless treatment is unsatisfactory so is, usually, complicated treatment. Furthermore, in the treatment of a patient he must not be asked impossibilities; there is no use in suggesting to a man things he cannot do, in order to get well. Just as our plan should be simple, so should it be exact; the patient must understand it clearly. Hence it is important that the physician write down for the patient the chief things he wishes him to do; the diet, for instance, or general scheme of life that the physician wishes him to follow. The next point about your plan that you are to remember is that it must be *directed to an individual*, and not to a disease. Remember always that you are dealing, not with a mechanism that has gone wrong, but with an individual who has a physiological personality, in which he differs from all other persons, and your treatment must be so directed as to recognize that fact. Further, you must avoid all fads in treatment, and you must be *conservative*. "Don't be blown about by every wind of doctrine; don't take up every new thing that is brought forward in the way of treatment." Private practice is not the sphere in which to try experiments. Be sure a new treatment is going to be better than the old before you adopt it. If your treatment is conservative, it should also be *eclectic*. Your plan of treatment may be either *radical* or *symptomatic*. Radical treatment is that which goes to the root of the disease. When you cannot adopt radical treatment, you must do the next best thing, adopt symptomatic treatment, that is to say, treat the symptoms as they arise. Sometimes treatment must be "expectant." It is often the business of the doctor to hold a watching brief for his patients, looking out for complications and dealing with them in time. It is the inaction, not of ignorance, but of the man who knows when it is well to intervene and when to hold his hand. As treatment may be radical or symptomatic, so remedies may be either *rational*—largely corresponds to symptomatic. There is a perfectly legitimate ground for the use of the empirical remedy. The *methods of attack* at your disposal in carrying out your plan of treatment may be grouped under (1) general management, (2) diet, (3) medicinal line of attack, (4) specifics, (5) physical methods, (6) psychical treatment or psychotherapeutics, and (7) operative measures. The object of general management is to put the patient in the best possible condition in which to fight his disease. Always be able to give to yourself, and if necessary to your patient, a definite reason why any particular food is forbidden. If an article disagrees with the patient, you should not cut it out of his diet altogether, but rather reduce the amount of it which he takes. When you have to make a change in the patient's diet, make it gradually, that is, if it is a big change. As a concession to popular prejudice you may have to prescribe drugs when you know they are not needed. Again, it is quite possible to underestimate the part which drugs can play in treatment. Psychotherapy plays a considerable part in the treatment of disease. Coleridge remarked long ago, that in chronic nervous ailments, "he is the best physician who is the best inspirer of hope," that is, the suggestion that the patient is going to get well. You must also recognize the limitations of treatment. It is important to be able to recognize when you are beaten. When that time comes, when Death holds all the trump cards and you see the game is up, do not torment your patient by sitting at the bedside of the dying man injecting stimulants into him.

La Presse Médicale.

September 22, 1919.

Clinical Forms and Treatment of Adrenal Insufficiency.—Sezary has isolated three types or genera of symptoms. The first is sudden death due to a fulminating insufficiency. Next in order are the syndromic forms which comprise an acute form—the Sergent-Bernard syndrome, the ordinary subacute, and the Addisonian form (Addison's disease), the latter being eminently chronic. Finally we see monosymptomatic forms such as myasthenia. The first mentioned form is merely one of the causes of sudden death in the midst of health and after surgical operations, anesthesia, etc., and the author says hardly anything about it. He distinguishes from it the Sergent-Bernard syndrome because the latter is an expression of Addison's disease which sometimes develops on a background of the latter malady and again as an abortive form of the latter. Practically, however, the two acute forms must be the same, s there would be no room for two separate affections so closely related. The Sergent-Bernard syndrome is divisible into two clinical forms according as it occurs isolated or part of Addison's disease. The syndrome is as follows: atrocious backache and abdominal pains; repeated and perhaps incoercible vomiting; diarrhea or exceptionally obstinate constipation; prostration, hypothermia and low tension pulse; cold extremities and tendency to cyanosis and collapse; death in from 3 to 6 days and exceptionally sudden or in a few hours. This syndrome has been mistaken for acute poisoning, cholera, peritonitis, meningitis, and several other grave affections, including encephalopathies of various kinds. The same syndrome is also seen symptomatically in any grave general infection or intoxication. The typical and atypical forms of Addison's disease are now related and the author proceeds to mention bulbospinal myasthenia, otherwise the Erb-Goldflamm synrome, the adrenal nature of which has long been suspected. However, myasthenia is itself a syndrome of which the adrenal type is only one form. Finally there is a form of muscular atrophy of suprarenal origin. Under treatment it is insisted that the test for the indication for adrenaline therapy is the ability of the latter to maintain the blood pressure when this is depressed.

Granuloma Annulare.—E. G. G. Little reports a case of this kind in a girl, aged nine years, who was the daughter of a medical man practising in British India. The eruption had commenced twelve months previously while resident in India, and at that time there were numerous and characteristic lesions on the right medius and ring fingers, on the dorsum of the right foot, and a small efflorescence about the external malleolus of the same foot, and on the leg about the knee on both sides. In addition to the characteristic ringed lesions there were some small erythematous, not ringed patches the size of a threepenny-bit, on the legs of both sides. There was no tuberculous history. The child looked pale and somewhat thin.—Proceedings of the Royal Society of Medicine.

Book Reviews.

GYNOPLASTIC TECHNOLOGY. With a Chapter on "Sacral Anæsthesia." By ARNOLD STURMDORF, M.D., Clinical Professor of Gynecology, New York Polyclinic Medical School; Visiting Gynecologist, New York Polyclinic Hospital; Consulting Gynecologist to the Manhattan State Hospital; Fellow of the American College of Surgeons; Fellow of the New York Academy of Medicine; Fellow of the American Medical Association, etc., etc. Pp. 334, illustrated with 152 Half-tone and Photo-engravings in the Text, some in Colors, and 23 Full-page Plates, with 35 Figures, all in Colors. Philadelphia: F. A. Davis Company, 1919.

THIS is a very interesting book covering gynecoplastic work on the cervix, vulvovaginal, and contiguous structures, and, in addition, the discussion of certain correlated subjects. Sturmdorf has not followed the beaten track but has elaborated his previous contributions to the literature of these subjects. Many of his contributions have been based on original concepts or anatomical studies; and he has evolved much of great scientific interest and practical value. The book bristles with originality, sometimes affects the bizarre, but never stoops to the commonplace. For example, we find the rather unusual and striking word "Gynoplastic" on the back of the cover and on the title page; but this becomes the more generally used term "gynecoplastic" in the headings at the top of each left hand page and throughout the text.

Sturmdorf rails at the use of the curette, indiscriminate tracheloplasty, and amputations of the cervix in cases of endocervicitis—a subject to the discussion of which he devotes an unusual amount of space before describing his method of treatment. Before discussing his method of performing perineorrhaphy, which he calls "Levator myorrhaphy," Sturmdorf devotes several chapters to the discussion of the mechanism of intrapelvic visceral support, the levator and muscle, and the pelvic fascia. In the course of the latter chapter and in another further along in the book, we recognize quite a number of plates reproduced from Weiss's "Practical Human Anatomy." Unintentionally, no doubt, there is nothing on the plates or in the underlying legends crediting them to this source.

The author's operation for the repair of perineal lacerations is very carefully planned out on an anatomical basis and should give good results. We cannot agree with his statement that vaginal shortening of the round ligaments should constitute a part of every cystocele operation. Various methods of handling cystocele are described; and here, as in other parts of the book, historical data and the discussion of theoretical and practical considerations show the author's familiarity with the literature as well as his own comprehensive grasp of his subject. Among other important conditions discussed we find vesico-vaginal fistula; functional urinary incontinence, in the course of which chapter he calls attention to the not infrequent presence of supernumerary ureteral openings and indicates proper methods of treatment; fecal fistula; cancer and elephantiasis of the vulva; and congenital malformations and their treatment.

Sturmdorf's book is a really valuable addition to gynecological literature; and it should be an aid not only to the young surgeon but also, and perhaps particularly, to the specialist in this line. Mechanically, paper and press-work are excellent, the book is exceptionally free from typographical errors, and our only complaint in this respect is that the book is bound so tight that it will not lie open at a desired place without the use of a very heavy paperweight.

LA DYSCYTOGENESE HYPOCYTOPOIETIQUE DYSEUTROPHIQUE, OU CANCER. Par Docteur NAAME, Tunis. Paris: A. Maloine & Fils, 1919.

UNDER this formidable title the author presents his thesis that the cause of cancer is due to a disturbance in the function of one or more of the endocrine glands. He is not wholly convincing though he reports some astonishing results through the use of preparations of these organs. This small pamphlet must be regarded in the nature of a preliminary announcement and any decision must be reserved until the author is able to produce his evidence in full. Certainly he cannot be said to have proved his case with this publication.

THE MEDICAL CLINICS OF NORTH AMERICA. Chicago Number. Volume 3, Number 1, July, 1919. Philadelphia and London: W. B. Saunders Company.

THERE are seventeen contributors to this number and they present an interesting series of cases for the consideration of the reader. There is no doubt of the stimulating effect of the clinic upon the mind of the medical man and if he be isolated in a small town this effect should be all the more striking. Such publications therefore serve a valuable purpose and have a marked educational influence. Of the subjects presented in this number we would call attention especially to Hodgkin's disease, pulmonary tuberculosis and the radiographic diagnosis of bone affections. The various contributions are uniformly interesting.

LA TRICOMONOSIS INTESTINAL. Por El Dr. EDMUNDO ESCOMEL, Delegado dela Facultad de Medicina de Lima. Lima: Sanmarti y Cd., 1919.

THE author of this work is a prolific writer with especial reference to parasites and has considered the trichomonas in some of his earlier papers. He has studied the diarrhea and dysentery caused by this organism in his residential city, Arequipa, Peru, since 1898. This booklet therefore represents twenty years of continuous study. He had already reported 152 cases of dysentery due entirely to this parasite. He gives a page of conclusions, from which we learn that in addition to various enteric syndromes the trichomonas causes hepatitis, like its congener the ameba, and vaginal and gingival trichomonosis are likewise mentioned. The parasite has been found in the pus of Rigg's disease and in leucorrhea.

MEMORIAS DO INSTITUTO OSWALDO CRUZ. TOMO X. FACICULO. Rio de Janeiro: Manguinhos. Ano, 1918.

THE text of the five papers appear in Portuguese, followed by numerous detached plates; after which we find complete translations of the text into English. The individual papers deal respectively with the Fruit Flies of Brazil, Protozoan Parasites on the Polydora Socialis (a marine worm which bores galleries through the shells of mollusks), a new Human Mycosis (the Oidium brasiliense causes a new human disease), Brazilian Fresh Water Shells of the Genus Planorbia, and Schistosomatosis in Northern Brazil. The last work involved a journey of considerable magnitude in which the inhabitants of various communities were examined for the ova of trematode worms.

IRISH ETHNO-BOTANY AND THE EVOLUTION OF MEDICINE IN IRELAND. By MICHAEL F. MALONEY, B.A. (Hon.), R.U.I., M.B., Ch.B., N.U.I., L.A.H., (Dublin). Dublin: M. H. Gill & Son, Ltd., 1919.

THE text of this little book is English but the plant species have equivalents in Irish. The Irish terms are evidently in common use and never were literal translations of Latin and English terms. The Irish terminology is very rich—for example there are four names for the cranberry and several names for well-known plants are the rule. Comparison of general and special names is instructive. Thus the juniper is apparently a form of yew. On the other hand plants closely allied may have nothing in common in their designations, although this is exceptional. The second part of the work comprises a history of Irish medicine, which by the way should not be confounded with Anglo-Celtic medicine as taught in Dublin.

LA LOTTA CONTRO LA MALARIA MEDIANTE. La Grande e Piccola Bonifica e la Disinfestione Idro-Aerea Antanofelica. Per PROF. CLAUDIO FERMI, Dirttore dell' Instituto d'Igiene della R. Universita di Sassari. Roma: Tip. rell 'orpano-trofio di S. Maria degli Angeli, 1919.

THIS brochure is as its title implies devoted to the subject of mosquito disinfection. In addition to the prophylactic water sterilization of larvae the author deals with aerial disinfection, which is of course no other than fumigation and the use of butterfly nets and other contrivances to trap the full grown insect. The use of protective netting also comes under this heading. In addition to disposing of the insects, the traps are useful for obtaining laboratory specimens.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 17, 1919.

THE SECOND VICE-PRESIDENT, DR JOHN A. HARTWELL, IN THE CHAIR.

THE subject of the evening was "The Clinical Significance of Blood Examinations."

Cytology.—Dr. FRANCIS CARTER WOOD spoke briefly on this phase of the subject. He said that as a matter of fact in the morphology of the blood there was but little that was interesting and at the same time new. He would therefore be as brief as possible because he thought there was more of interest to be said in reference to the bacteriology, serology, and chemistry of the blood than in regard to the morphology. The knowledge of the red blood cells with which we were familiar still held good. The normal red blood cell was considered to be a disc, though occasionally healthy normal blood had a large proportion of red cells. Cases had been reported in which such a condition existed in an entire family of healthy people. The diagnosis of pernicious anemia was still dependent upon the examination of the blood, and in the hands of a trained worker this diagnosis could be made with a great deal of certainty. Cases of so-called pernicious anemia reported as cured in which the morphology was doubtful were probably not true pernicious anemia. The most characteristic feature of this disease was the blood picture, there being an increase in the size of the red cells, oval cells which were particularly characteristic. nucleated red cells, a lowering in the number of lymphocytes and a relative disappearance of the leucocytes. We might get a similar blood picture temporarily in sepsis or acute bacterial endocarditis, but it was not constant as in pernicious anemia. We had come to realize more and more that there was a type of cases in which the number of red cells was greatly increased, namely, the polycythemias. Sometimes in these cases the only physical evidence of the condition was an enlarged spleen, the blood count, however, might rise to 10,000,000 per cubic millimeter. The treatment of polycythemia was of interest because ordinary methods seemed to have no effect and radium and the *x*-ray did not depress the blood count. It was claimed that some cases had been benefited by the combined use of benzol and radium, and that under this treatment the disease was favorably influenced. Transfusion was now frequently done by various methods. An interesting feature in connection with the prognosis was the appearance of certain reticulated cells after transfusion. Observations on the behavior of these reticulated cells were made in the speaker's laboratory several years ago and it was noted that where there was an increase in the reticulated cells there was a permanent or fairly permanent result. In pernicious anemia if the blood was watched during four or five weeks after transfusion one could trace the corpuscles of the patient and those of the donor and could watch the gradual disappearance of the donor's cells. If no reticular cells appeared after the transfusion then the patient is only tided along for a short time; if, however, reticulated cells appear some regenerative capacity is present and we may expect an improvement for a time. The significance of leucocytosis in diagnosis was now generally recognized and the leucocyte count had become a routine practice and there was nothing especially new in it During the influenza epidemic, as had also been noted in the epidemic of 1893, there was usually a lymphocytosis in pure influenzal infections. In the treatment of myelogenous leucemia the use of one of the forms of radiation was now the accepted practice and in his experience in a certain number of cases it was of distinct benefit and prolonged life. Dr. Wood showed lantern slides demonstrating the alterations that took place in the blood of patients suffering from leucemia, and cited several cases. He described one case in which a blood showing 900,000 leucocytes and 1,000,000 red cells was changed to an almost normal condition under the influence of radiation and said that cases of this kind made it evident that something was accomplished by radiation. Basophiles, however, did not disappear under *x*-ray and radium. The excision of the spleen did not seem to have much influence in prolonging life in comparison with the *x*-ray and radium.

Chemical Changes in the Blood in Disease, Their Significance and Value in Diagnosis and Prognosis.—Dr. VICTOR C. MYERS presented this contribution in which he said that accurate data on the chemical composition of the blood, especially of the non-protein fraction, were the result of American observations with American methods. For the development of the methods which had made this work possible we were largely indebted to Folin, Benedict, and Van Slyke. The practical information made available by these methods had given very valuable data on just those conditions on which the older methods of blood examination, cytology, bacteriology, and serology, gave little information, namely, such constitutional conditions as nephritis, diabetes and gout. Chemical methods applicable to the study of the blood covered a rather broad scope, including methods for the estimation of the blood volume, the blood proteins, serum albumin and globulin, improved methods of hemoglobin estimation; methods for the determination of non-protein nitrogen and its individual components, urea, creatinine, uric acid, amino acid nitrogen, creatine, and ammonia; methods for the lipoid constituents, fat, lecithin and cholesterol; methods for the mineral constituents, chlorides, phosphates, calcium, magnesium, potassium, and iron; methods for blood gases, carbon dioxide and oxygen, and methods for the hydrogen ion, the acetose bodies, phenol, and such enzymes as diastase, catalyse, etc. As already pointed out these methods had yielded especially helpful information in diabetes, nephritis, and gout, while the data obtained in renal diabetes, infantile conditions such as tetany and cyclic vomiting, in eclampsia, malignancy, cholelithiasis, pernicious anemia, disorders of the ductless glands, and various urological conditions, had given us a new point of view regarding many of these disorders. That the tests furnished information of very great value in the diagnosis, prognosis, and treatment, in the conditions to which they applied was indicated by the following brief summary of the practical value of the various tests. *Diabetes*.—In this condition the examination was primarily directed to the determination of the sugar, although in advanced cases the acidosis, as indicated by the carbon dioxide, might assume greater significance. Here the condition of lipemia might develop, and of this the cholesterol was a particularly good index. It should be remembered that the excretion of sugar by the kidney was simply one of the body's many factors of safety. The real condition to which attention should be directed was the hyperglycemia, and as the disease advanced the glycosuria became less and less a safe criterion of this, since the permeability of the kidneys for sugar appeared to be gradually lowered. Normally the blood sugar varied from 0.09 to 0.12 per cent., and in early cases of diabetes one might note an excretion of sugar when the sugar of the blood rose above 0.16 or 0.17 per cent., but in advanced cases showing nephritis symptoms blood sugar figures of 0.2 to 0.3 per cent. (and even to 4.6 per cent.) might be noted without the appearance of any sugar in the urine. The writer and his colleagues had observed that the diastatic activity of the blood was proportional to the blood sugar in untreated cases, and appeared to be the blood sugar determinant. In those cases which developed a severe acidosis, the carbon dioxide determination of Van Slyke was a much more reliable and valuable index of the acidosis than any urinary determination. Any extended medical or surgical interference should not be attempted on a severe diabetic without a knowledge of the blood sugar and the alkali reserve of the body as indicated by the carbon dioxide of the blood. *Renal Diabetes*.—The diagnosis of this uncommon condition could be made only when a knowledge of the blood sugar content was at hand. Broadly considered, renal diabetes might be regarded as a condition of glycuresis not dependent upon a temporary increase of blood sugar in an individual free from symptoms of diabetes mellitus. *Nephritis*.—There appeared to be little doubt that early cases of nephritis were accompanied by an appreciable rise in

the blood uric acid, although a rise in the blood urea could probably be taken as a safer sign of impaired kidney function. It was certainly true that the urea nitrogen fell within very narrow limits for perfectly normal individuals. As soon as one passed to hospital patients, however, figures above 15 mg. of urea nitrogen were found. Figures over 20 on the usual restricted protein diet of the hospital would suggest impaired kidney function. Creatinine appeared to be more readily eliminated than either uric acid or urea and it was not, as a rule, until the blood urea had doubled, or more than doubled the normal, that there was an appreciable increase in this purely endogenous waste product derived apparently from muscle metabolism. The normal for the creatinine of the blood was approximately 1 to 2 mg. per 100 c.c. and more than 3.5 mg. could be viewed with grave concern, while figures over 5 mg. were almost invariably indicative of a fatal termination. The only possible exceptions were cases in which the retention was due to some acute renal condition. The inability to properly excrete the waste products of nitrogen metabolism was only one of the difficulties which arose as the result of renal disease. In parenchymatous nephritis, or nephrosis, the edema was probably dependent, in part at least, on the lowered permeability of the kidneys for chlorides, with their consequent retention. It was natural therefore to expect that the excretion of other salts would be deficient, although they had only recently come to appreciate the effect of the excretion of phosphates. When the phosphate excretion was impaired, bringing about an increase in the (acid) phosphate of the blood (and tissues), an acidosis resulted, which might be quite as severe as that resulting from diabetic ketosis, judging from the carbon dioxide combining power of the blood. In this connection it was noted that many advanced cases of malignancy, possibly as a result of toxemia, gave the chemical blood picture of moderately severe nephritis. Nitrogen retention and acidosis of nephritis were worthy of consideration from a surgical as well as a medical point of view, especially when one considered the influence of anesthetics on acidosis.

Urological Conditions.—As had been shown by Squier and Myers the blood urea had been found to be a very valuable preoperative prognostic test in cases of prostatic obstruction. Cases showing nitrogen figures under 20 mg. per 100 c.c. of blood might be regarded as good operative risks so far as the kidneys were concerned. When the urea nitrogen figures were between 20 and 30 mg., and especially between 25 and 30, the patient should be operated on with considerable caution and best after a period of preliminary treatment directed to relieve the nitrogen retention. With urea nitrogen figures over 30 mg. the operative prognosis was bad. Dr. Myers then elaborated his subject by lantern slides, showing the chemical constituents of the blood under normal conditions, the alterations that occurred in various pathological states, and reviewed the findings and discussed their significance in a number of their cases. He also referred to the subject of diet in nephritis and showed a typical diet, low in nitrogen and containing 1,424 calories, which was suitable for severe cases.

The Bacteriology.—Dr. E. LIBMAN spoke on this phase of the subject. He stated that he would attempt to discuss only the significance of bacteriological examinations of the blood. Before he entered into the subject, however, he stated that it was necessary to be careful in the use of the terms one employed. He pointed out that the terms septicemia and pyemia should be entirely dropped. Instead of the term septicemia, one should say general infection or bacteriemia, if the primary focus could not be found. If the local infection could not be found, the general infection which occurred secondarily was a cryptogenic bacteriemia. Instead of the term pyemia he used the term metastatic infection. Such metastatic infections were generally due to a preceding bacteriemia but it happened at times that the metastatic foci were developed because pieces of thrombi were broken off from the vein near the site of the primary infection. In such an instance there might be no free bacteria in the blood and the cultures would remain negative. He drew the distinction between terminal local and general infections and those which he called terminating. Properly speaking a terminal infection was an infection which occurred in a patient who was suffering from a disease which one was sure would within a short period (weeks or months) prove fatal. If such a patient happened to be exposed to infection he might die a considerable period before the time at which he would have died from the disease had it been uncomplicated by any infection. A terminating infection he considered to be one which occurred in a patient who evidently had a very short time to live and who incidental to the ending of the illness developed a pneumonia or an erysipelas or some other form of local or general infection. An agonal invasion was one which occurred when the patient was moribund. Dr. Libman cited instances which showed that the question of general infection was a variable one depending upon the type of the primary infection. For instance, in erysipelas there was usually no general infection, a positive blood culture being obtained only in fatal cases or in cases accompanied by other conditions, or in instances of erysipelas of the mucous membranes. Another disease in which there was rarely a positive blood culture was abscess in the lactating breast. In cases of liver abscess there was usually no general infection. In diabetes, considering the frequency of local infections, it was remarkable how infrequent general infections were. It seemed that general infections were less common when the local infection was in a tissue containing a large amount of carbohydrate. Appendicitis did not generally give a positive result and the same held true of peritonitis of intestinal origin. A pyelonephritis secondary to bladder infections was much more apt to result in general infection than was a pyelitis of pregnancy. In cases of thrombosis of the pelvic veins positive blood cultures were relatively infrequent. In pylophlebitis general infections were very rare, whereas they were not unusual in cases of infections of the gall ducts. All these remarks had reference to aerobic organisms. In cases of infection of the pelvic veins and in cases of pyelophlebitis, anaerobic general infections had been found. In cases of sinus thrombosis, he had on previous occasions shown the great frequency of general infections and the value of a positive result for diagnosis. It had been observed that one did not find general infections from mastoiditis or otitis media, but did get positive blood cultures when the meninges were involved or the lateral sinuses. In rheumatic fever the blood cultures were generally negative except for the occasional finding of a hemolytic streptococcus infection. This streptococcus was not considered the cause of the disease, since it was present only occasionally and because the complement fixation test proved uniformly negative. The negative results in cases of pyelonephritis were valuable in making a differential diagnosis between that condition and acute infections of the valves of the heart. In cases of acute infections of valves of the heart the blood culture was practically always positive. (It was best to make two cultures.) The Gram negative organisms as the cause of general infections were then discussed and attention was drawn to the point that such organisms as the *Micrococcus flavus* and the *Micrococcus endocarditis rugatus* had been mistaken for the gonococcus. After discussing the rôle of the *Bacillus proteus* and the Friedländer bacillus and the significance of bacteriemia in cases of osteomyelitis, Dr. Libman discussed the significance of bacteriemia in general and pointed out that when bacteria were found in the blood one must determine whether they represented the infection from which the patient was really suffering or whether they represented an intercurrent traumatic or terminal infection. By traumatic or operative bacteriemia was meant one arising after operative procedure, especially on the bones, or after cystoscopic examinations. Such infections should disappear within 24 to 48 hours. The difficulties of decision in cases in which there were two or more local infections each due to different organism were gone into. It was shown that in every case of bacteriemia it was important to find and eradicate the primary focus. He presented considerable evidence to show that bacteria as a rule did not multiply in the blood. If they were not kept in the blood by an endocarditis they were being thrown into the blood from a primary focus. Figures were obtained from cases of sinus thrombosis before and after the jugular vein was

ligated. From these Dr. Libman had been able to get definite data as to the rapidity with which bacteria disappeared from the blood after the local infection had been properly treated. Positive and negative blood cultures were usually of value only if they were interpreted by those who had wide clinical knowledge especially in infections.

Serology.—Dr. Joseph Gardner Hopkins discussed the value of agglutination tests in the clinical diagnosis of infectious diseases. He stated that in typhoid and paratyphoid fever the Widal reaction as ordinarily performed had lost most of its former value on account of the widespread use of prophylactic vaccines, which of themselves stimulated the production of agglutinins. Vaccination against typhoid or paratyphoid was followed by a rapid production of agglutinins, the curve rising to a sharp apex in from one to two weeks after the last injection and then falling, very rapidly at first and later more and more slowly, not reaching normal for a year or two. In typhoid fever the agglutinin curve was somewhat similar. In a patient who had been vaccinated the curve was similar but started at a higher level and did not return to normal as promptly. If one examined the serum from a vaccinated case several times during the second or third week of illness he would find the titre rapidly increasing, or during the third or fourth week he would find it falling; therefore the actual amount of agglutination found on one determination was of little significance because it was largely dependent upon previous vaccination, but a typical rise or fall of the titre on successive determinations was of diagnostic value. The technic must be standardized in order that the results of the successive tests might be comparable, and the interpretation of the findings required some experience, as paratyphoid or at times wholly unrelated infections would cause fluctuations in the amount of typhoid agglutinins. The test was of aid in diagnosis but could not be relied on as absolutely as the Widal in the unvaccinated.

Agglutination in Other Infections.—In bacillary dysentery the infection was usually limited to the intestinal mucosa and agglutinins were not developed as regularly as in typhoid fever and some patients never showed a characteristic rise, though it occurred in many cases. An agglutination of the Shiga bacillus in dilutions of 1-50 or higher might be considered diagnostic of past or present infection. In the Flexner type, however, agglutination was not diagnostic unless it reached 1-250.

The Complement Fixation in Gonorrhea.—In deep-seated infections by the gonococcus, complement fixing antibodies had been found fairly constant in the blood. The reaction was therefore of special value in such conditions as arthritis and epididymitis, and to a less extent in prostatitis and chronic urethritis. It was also widely used to determine when a cure was obtained. Quite recently Captain D. Thomson of the British Army had described a new method of preparing the antigen, for which he claimed a high percentage of positive reactions. He reported that of 248 cases of all types, 92 per cent. gave a positive test at the end of the first week. None of the workers had so far reported on a large series of non-gonorrheal cases and one was impressed by the fact that such a study was needed.

The Complement Fixation Test in Tuberculosis.—The interpretation of the complement fixation test in tuberculosis was difficult. The antibodies were not found in all cases of clinical tuberculosis and they were present in not a few persons who had no clinical symptoms, though these doubtless harbored a latent infection. They were found more constantly in the later than in the earlier stage of the disease, and more constantly in active than in inactive cases, but a positive reaction was not proof that a case was advanced or that it was active. Among the rarer infections there were two in which the complement fixation test seemed of definite value, namely, glanders and echinococcus cyst.

The Wassermann Reaction.—It was generally agreed that this reaction appeared from two to eight weeks after the development of the initial lesion, that it was present in nearly 100 per cent. of active secondary cases if uninfluenced by treatment, and in 80 to 90 per cent. of tertiary cases. About 70 per cent. of tabetics showed the reaction in the blood, and an additional 20 per cent. would give the reaction if the spinal fluid was examined. As to congenital lues there had been few statistics published, but Craig reported 82 per cent. positive results. Yaws, recurrent fever, and a considerable proportion of cases of trypanosomiasis and leprosy gave the reaction. To these exceptions might be added malaria and scarlet fever in the febrile stage and blood taken during anesthesia and postmortem, though there was conflicting evidence in the last four conditions. It would seem that when one investigator obtained positive reactions in a number of conditions in which the majority of investigators had found the blood negative, it might be concluded that the technic of this individual investigator was at fault. The only way in which a serologist could determine when his tests were too sensitive was by the appearance of such false positives. In a suspected primary sore if the Wassermann remained negative for two months syphilis might be practically excluded. In a suspected secondary lesion, untreated by arsenic or mercury, a negative Wassermann, repeated to avoid error, practically ruled out syphilis. In the question of tertiary or parasyphilis a negative Wassermann was by no means conclusive, but certainly weighed against the diagnosis of lues. In interpreting negative reactions one fact should not be forgotten, and that was the finding of Craig and Nichols, that if the patient took a large amount of alcohol he might temporarily convert a positive into a negative reaction. Another serum reaction that had proven of practical value was the testing of the donor's and recipient's blood before transfusion for iso-agglutination. There were two new developments along this line which were of interest. One was a simplified method of making the tests, devised by Major Lee, which proved useful in the A. E. F. To make this test the only paraphernalias required were a glass slide, a needle and a vial each of group II and group III serum, to which a little citrate or phenol had been added. A small amount of blood from a finger prick was mixed with each of the sera on the slide and the reading made with the eye in two or three minutes. With the technic so simplified the emergency could rarely be so great that transfusion could not be delayed until the group of the recipient and proposed donor had been determined. The other development was that according to the observations of Shawan and Masson, the success of iso-skin grafts was dependent on the same factors and a graft would not take if the donor's red cells were agglutinated by the patient's serum.

Stated Meeting, Held May 15, 1919.

The President, Dr. George David Stewart, in the chair.

The program of the evening was presented in cooperation with the Section on Neurology and Psychiatry, and consisted of a "Symposium on Alcoholism."

What Constitutes an Intoxicating Beverage?—Prof. C. P. Sherwin presented this communication by invitation. He first quoted a number of definitions that had been given of the terms "intoxicating" and "beverage." From these it seemed that the term intoxicating beverage, drink, or liquor, in the absence of a statutory, definition was understood to include any liquor intended for use as a beverage or capable of being so used, which contained such a proportion of alcohol that it would produce intoxication when imbibed in such quantities as it was practically possible for a man to drink. New York held that the term "intoxicating liquor" did not apply to a beverage containing so small a percentage of alcohol that the human stomach could not contain sufficient of the liquor to produce that effect. Most legal, medical, and scientific works failed to give us a definition of intoxication. The term was used to designate the condition of a person who had been brought so under the influence of alcohol by successive imbibitions during a short space of time as to be unable to control his actions intelligently and sensibly, but should not be confined exclusively to alcohol. It was of course impossible to lay down a hard and fast rule as to what would cause intoxication. What intoxicated a man today would not intoxicate him tomorrow, if taken in the same amounts and

apparently under the same conditions. What produced one of the cardinal symptoms of intoxication in one man would produce no like response in another, when the same beverage was ingested in twice the amount. Whether this was physiological, psychological, chemical, or just idiosyncrasy, could not be determined and likely never would be, but there were several conditions, both of a physiological and chemical nature, which must be taken into consideration even before the small amount of available data might be intelligently interpreted. To what extent, if at all, did solutions of ethyl alcohol, or grain alcohol in water, as commonly used in laboratory experiments, differ in their action on the nervous system from ordinary alcoholic beverages of corresponding strength, such as beer, wines, or spiritous liquors? In beer the amount of alcohol varied between 2 and 4 per cent.; in light wines from 6 to 10 per cent.; in heavy wines from 10 to 18 per cent.; in spiritous liquors from 30 to 70 per cent. In beer there were few substances other than alcohol which tended to produce intoxication in any form. In wines, however, there were other substances, as for instance the "volatile boquet," consisting no doubt of esters of ethyl and higher alcohols which must be more toxic than alcohol itself. In spiritous liquors there were many factors besides alcohol which tended to produce intoxication to even a greater extent than the alcohol itself. Among these were the aldehydes, particularly furfural, ethers, and higher alcohols. In certain grades of whiskey traces of allyl alcohol had been identified and, so far as known, this was perhaps the most toxic of the alcohol series. As little was known concerning the rate of absorption and the process of elimination of these latter named substances, no definite conclusions might be drawn from experimental work where alcoholic solutions alone were employed. Researches carried on at the University of London tended to show that there was a decided difference in the action of these different alcoholic beverages on the gastrointestinal tract, likely due to some content other than alcohol. There was also a more marked intoxication following the ingestion of a diluted spiritous liquor than when an equal volume of beer of the same strength was employed. From a scientific standpoint there was nothing to substantiate the popular belief that the mixing of drinks tended to increase the degree of their toxicity. The general consensus of opinion seemed to be that when alcohol was administered in greater dilutions there was a decreased rate of absorption hindering a rapid concentration of the alcohol in the blood stream and subsequently reducing the degree of intoxication. Experiments had demonstrated beyond doubt that alcohol was much more toxic when taken on an empty stomach than when ingested with food or taken after meals. It had been claimed by some that perhaps the fats tended to inhibit the rapid absorption of alcohol. Atwater, Billings, Chittenden, and Welch drew the conclusion from experiments performed by them that alcohol in moderate quantities, say one pint of wine containing 10 per cent. alcohol, had no direct action on the heart itself, either in the way of stimulating or depressing it, at least as based on experiments covering a short period of time. It also had no action on the peripheral or central nerves which controlled the rate or force of the heart. In moderate quantities it had no appreciable effect on the arterial blood pressure. When a change did occur it was in the direction of a fall and not a rise. Alcohol in small amounts, as one pint of light wine, was a respiratory stimulant of moderate power for human beings, but much greater when corresponding amounts were fed to animals, particularly rabbits. The stimulation of alcohol and alcoholic beverages was greater in fatigued persons than in those who were in no wise exhausted. Increased heat dissipation always followed alcoholic ingestion. The compensatory increase in heat production necessarily following required increased oxidation and subsequently an increased demand for oxygen due to increased oxidation. Fifteen, thirty, and forty-five grams of alcohol, were ingested in the form of five per cent. solutions and these moderate quantities of alcohol were found to shorten simple reaction time. Larger quantities of wine, such as a pint of wine 10 per cent. alcoholic strength, was found to lengthen the time of all simple operations, such as adding up columns of figures, reading accurately scientific data, or taking fine scientific measurements. Large quantities of wine, such as two pints of a 10 per cent. wine, caused in most subjects undergoing experiment a lack of control of the emotions, noticeably affecting the power of attention, of clear judgment and reason, and decidedly lowering the acuteness of the several senses. The writer quoted the opinions of several different men in regard to the toxicity of alcoholic beverages and referred to the report of a committee appointed by the British Government to investigate the liquor problem in the United Kingdom. Experiments were described in this report from which it was ascertained that animals began to be slightly affected when the proportion of alcohol in the blood reached the level of 0.12 per cent. With higher proportions the symptoms became more marked and a profound stupor, frequently ending in death, ensued when the alcohol content rose to 0.72 per cent. Similarly in cases of drunkenness in man, the blood was found to contain in one observation 0.15 per cent of alcohol and in another instance, when the intoxication was more pronounced, 0.23 per cent., and it was generally accepted that with a blood content of over 0.6 per cent. alcohol there was a considerable likelihood that profound stupor or death would ensue. Alcohol passed rapidly from the stomach and bowel into the circulation and, owing to the slowness with which it was excreted, the amount in the blood soon reached a maximum level bearing a pretty constant ratio to the amount originally drunk. So that knowing the amount of alcohol originally drunk and the body weight of the drinker, one could at once give an approximate estimate of the maximum proportion of the drug which would be found in the circulation, and, conversely, one could say what amount of alcohol must be administered to give any particular percentage in the blood. Thus taking the proportion of 0.15 per cent., which was found in the blood in lesser pronounced cases of intoxication, in a man weighing 140 pounds, a total dose of 3½ ounces of absolute alcohol, nearly a gill and a half of whiskey, or rather more than four pints of beer of four per cent. strength, would be required to produce a less pronounced intoxication. According to experiments cited it would seem that 40 grams of alcohol was about the maximum dose of alcohol in one and one-half liters of the solution which would produce very slightly toxic symptoms in a normal individual.

Alcoholism and Personality.—Dr. A. A. BRILL read this paper in which he described the primitive condition of man when everything was simple and he craved no wine, no salt, no spices, no pretty combinations of color, and no pleasing combinations of sounds. With the advancement of civilization things gradually changed, and became increasingly complicated, until they culminated in the vast civilization of today. The individual was dominated by hunger and love, and the civilization of the individual like that of the race was best judged by his attitude toward these impulses; the most advanced races were those who had exercised the greatest control toward these impulses. Studies made of the highest types of individuals showed that natural impulses could only be controlled, never annihilated, and that there was always a constant struggle between them and the forces of civilization, and that society must often assist the individual if he was not to succumb in this struggle. The tastes of the child like those of the savage were very simple, the child only showing a versatile attitude toward nourishment as he grew older. He had collected data from hundreds of patients and with few exceptions no one took kindly to alcoholic beverages that did not taste sweet and most of them had to force themselves to drink whiskey, brandy, or beer. Gradually they not only became used to it but in most cases it became a habit. He had found that non-alcoholics did not reach the point where they took a drink "because they liked it" before the age of 19 or 20; the alcoholic developed a strong craving even for hard stuff at the age of 15, 16, or 17. With very few exceptions all the writer's chronic alcoholics were bad psychopaths, many were slightly subnormal, some were manic depressive types, and some epileptics. His experience in both hospitals and private practice led him to state that practically all individuals who chronically indulged excessively in alcohol were emo-

tionally more or less diseased. A psychiatrical examination would not show them all to be mentally deficient, though a great many of them were that, but judging by a standard of adjustment of continuous effort in some direction they were all deficient. He had treated them in all sorts of ways, had given them the so-called specifics, hypnotized and analyzed them, but the results were very disappointing. As a rule if a patient was not very subnormal he could be helped to give up alcohol for a while but he usually returned to it. The author cited several cases in which when alcohol was taken away the subjects had turned to other vices. A curious mechanism in one of his alcoholics was that the alcoholic indulgences alternated with attacks of eating during which the patient gorged himself with food. In this connection he mentioned that attacks of over-indulgence in food were not confined to alcoholism, but that he had seen a number of psychoneurotics who had regular eating attacks which served the same mechanism as drinking. When one studied such cases and compared them with the peculiar cravings in socalled normal and primitive people, one became convinced that chronic alcoholism was a psychoneurotic symptom usually found in emotionally defective persons, which in the normal was nothing but a craving or habit confined to the oral or gastric regions. It was usually induced by environments but when that particular craving was removed by treatment or force from the defective person something was bound to take its place either in the physical or the psychic spheres. The answer to the question why people both normal and abnormal indulged in some sort of beverage besides pure water was very simple. The wish was the motive force of life. Our wishing was done through our senses, and there was a tendency on the part of every individual to gratify these wishes and even overindulge them. Usually the average person learned to curb his wishes and allowed himself a certain amount of indulgence which was not harmful to him. No one could absolutely renounce a pleasure once experienced. It was as indestructible as physical matter; its form only could be changed. Anything that was as universally craved as fermented liquors must supply a definite want in the vital economy of the individual. Man always found it difficult to face inexorable reality and to avoid it he resorted to all sorts of psychic and physical means. Moderate doses of alcohol removed inhibitions and made reality less burdensome. While he in no way wished to be understood as favoring the American bar, he felt that the glass of beer or wine actually helped the laborer to feel more contented with life and allowed him to give vent to the play instinct which reality denied him and which his organism demanded. He was opposed to absolute prohibition of alcoholic beverages because the average normal person was hurt by it, the abnormal types would be made more abnormal through it, and society would undoubtedly lose by it, as it would put a premium on dishonesty and hypocrisy of which we had quite enough.

Some Psychological Aspects of Alcoholism.—Dr. L. Pierce Clark presented this paper, in which he stated that it was well known that alcohol served many functions. At one time it might paralyze the repressive forces of social custom and make free and natural ordinary social intercourse. At another time it might enable a person to rise to an intellectual and emotional height which he felt inadequate to do without the stimulating support of alcohol. At still another time it made it easy for an individual to express certain unconscious desires and demands which he could not do under other circumstances. Careful study thus revealed that the use of alcohol was dangerous largely to those individuals who used it to gain in an unnatural manner these feelings of rapport. If proper study of all the factors concerned in alcoholic indulgence was not made and pains taken to set these motives right, we might expect upon a mere prohibition of alcohol that we should have a number of other neuroses and psychoses materially increased thereby. It was perhaps of no material moment whether the potential nervous invalid broke into a neurosis or a psychosis, or whether he displayed his invalidism by alcoholic indulgence, but we should not look upon the mere prohibiton of alcohol as a terminal effort on our part to set matters right. To do this required a sober analytical judgment and a willingness on the part of the people as a whole to expend more effort and pains in adjusting social and economic conditions that made alcohol at present such a seeming menace, but which in reality was a result rather than a cause. The superficial and conscious motives for alcoholic indulgence had been handled so completely and were so current in the minds of most individuals that it was hardly necessary to enumerate them. The surprising fact was that so few corrective results were brought about in the every day world by merely recognizing them as such. It went to show that the underlying factors in the unconscious were really the determining ones for such a deep-rooted habit and indulgence. If we frankly recognized that bisexuality was inherent in every one and that certain tendencies, like companionship and brotherhood of one's own sex, were a real part of the normal emotional development of every adult, then we came nearer to understanding what some of the repressed forces were in the individual that required satisfaction. The author cited cases showing the strength of the subconscious homosexual tendency and stated that this was only one factor in the alcoholic psyche. Doubtless to this was due the growing addiction to drink among women, the breaking down of social barriers, opening new occupations, desire to do as men did, etc., but these were not sufficient in themselves to explain this. The formerly unjustly laughed-at social tea was the sublimated expression of feminine homosexuality; but alcohol was more satisfactory, therefore reserved for men. The virile component of woman was stirred today, and this helped to explain woman's increased turning to alcohol. Freud had shown that homosexuality was also responsible for alcoholic jealousy. The masochistic company sought out by chronic drinkers showed itself in the questionable company sought by chronic drinkers. One often found this otherwise unaccountable desire to sink socially in drinking periods. Also there was a certain feeling of quiet. Certain atavistic tendencies were also found in the jealous drinker. Atavistic reminiscences also played a large rôle in alcoholic psychology. There was also a sadistic component which not only explained duelling but was also a key to the numerous delinquencies and crimes that so notoriously accompanied alcoholism. Alcoholism numbed the higher functions. The psychosensory and motor protective mechanisms were enfeebled. Fortunately all drinkers did not become criminal, still alcohol permitted hidden criminal desires to work out. The sexual component alone did not explain the behavior of alcoholics; the whole psychic content must be considered. Many crimes seemed to be discharges of the need of a "howling drunk." This was one of the profoundest needs of human nature. The desire to transcend oneself also showed itself as a desire to forget. Chronic alcoholism tended to produce all sorts of memory disturbances; powers of observation were diminished; orientation to time and space were lost, and the individual lived in a phantasmagoric world. Physiological as these results might be there was also to be considered the complex of amnesia, the will and wish to break the chain of personal continuity. Here again was the desire to transcend the ego. The other expression of this desire was suicide. Rather than employ a loose, all-embracing mechanism of the sadistic-mascochintic principle, the writer thought it easier to say that the unconscious had different depths or levels and that in different degrees of intoxication we released varying levels of unconscious strivings and conflicts. That all alcoholism held a homosexual component might be true, but it was not at all clear in every case. And even when found there were many other autoerotic, heterosexual, and maternal fixation principles brought out in many cases, and not infrequently in one and the same case. This new conception of the psychology of the alcoholic made obvious the innate faults of the instinctive life, the fixation in the evolution of the emotional life, and showed us the pattern plan of what sort of training-out and social readjustment was necessary to heal such individuals. Although the study showed the truth of the contention that the line of treatment must always rest upon the individual and social analysis of the particular subject under consideration, and that here, as in other profound neuroses, analysis, and even routine psychoanaly-

sis, might be undertaken but that as a whole the confirmed alcoholic was by far a less favorable subject for pure analytic treatment than almost any other neurosis. In speaking of the demobilization of the saloon on July 1, Dr. Clark said men went to the saloon for good fellowship as well as for alcohol. The bartender himself was usually a good practical psychologist of human nature, and not only prepared the favorite tipple for his customer but also with quick, though sometimes spurious sympathy furnished him with the mental comfort he needed. Perhaps the bartender might be considered a sort of lowbrow canteen worker or Y. M. C. A. assistant, and perhaps all three could work together in the new saloon. At any rate, those who had charge must assume some of the nature and behavior of ordinary individuals and avoid the wearing of special dress or uniforms suggestive of inhibitions and prohibitions of certain aspects of society that had grown to be intolerant of the average individual. Perhaps the bar should be kept with its polished mahogany, its shining glassware, and the brass rail for the weary foot of the periodic visitant. There was no good reason why music might not be added to the new saloon with a chance to sing. Pool and billiards should be reunited with the saloons wherever they had been divorced. Cards, athletic games, motion pictures, reading rooms, etc., might also be added, and even four-minute speakers. Here would be a ready made audience for the politician and the social reformer. There was no reason why the saloon and the movement for social and community betterment should be strangers. The new order could not stop with the mere prohibition of alcohol without a positive and constructive program to meet in some measure the human craving expressed in alcoholic indulgence. For back and beyond the saloon were many social and economic evils which must be recognized fully and met squarely by all of us if we were to dismiss King Alcohol from his disastrous reign and dominion over the mind and body and make the world safe for human kind.

Alcohol in Its Social Compensatory Aspects.—Dr. Smith Ely Jelliffe spoke informally on this phase of the subject. He said in part that being the last speaker of the program he was somewhat at a disadvantage as those who had preceded him had said many things that he had intended to say and also because it was necessary after listening to others speak to recast one's viewpoint. He held no brief for alcohol, nor on the other hand did he maintain that it was responsible for the crimes so universally attributed to it. In view of the historical facts that from the earliest times men were found indulging in alcohol in the form of fermented fruits, figs, bananas, and other fruit, and that alcohol was used widely in the religious ceremonies of many different religions, thus reaching and permeating even to the divine, we must recognize that the problem was a very complex one. Many investigations had been made in the attempt to reach an explanation of the great hold this material had on various types of peoples for thousands of years and what made it so desirable. In seeking such an explanation he would like to call attention to man as an energy system, to consider for a moment the mechanism by which a human being captured, transformed, and released energy. Man created little energy within himself, he merely captured, transformed, and released energy through receptors, connectors, and effectors. The receptors were capable of capturing specific kinds of energy and of transmitting it with incredible speed and in amounts that could not be comprehended. To show the extreme sensitivity and the work done by even the simplest animal mechanisms Dr. Jelliffe alluded to experiments made by Harvey on medusæ which had a very simple system of receptors which he completely removed by an appropriate technic. Then by means of mechanical stimulation he was able to show that the stimulus traveled 457 miles in eleven days before it stopped. Yet the medusa had only 16 sense organs while the human being had millions of these sense organs and was taking in many billion times as much energy as the medusa. The dietitians stated that man received his energy from the three or four thousand calories of food that he ate daily. The energy generated by that amount of food was equal to approximately 250,000 foot pounds, yet to accomplish the excretion of urea from the blood into the urine required at least 2,000,000 foot pounds of energy a day. Where then was the energy to be acquired for all the other functions of the body? The food did not supply the energy of the body but only supplied the material for transforming energy. The energy came from outside the body, from cosmic sources, from heat, sound, light, gravity, inertia, etc. The most important feature in the capture and delivery of energy for the human body was the development of the organs of language and those energy containers which we called ideas or symbols. How did alcohol affect the body? This was through the interaction of receptors and connectors at points of contact which we called synapses. He could not go into the development of a synapsis, he said, but merely wished to call attention in a general way to the mechanism of which they formed a part. The receptor received a stimulus which traveled a certain distance along a nerve fiber. It then met with a mechanism which might be likened to a spark plug, namely, a synaptic junction, and here it met with a certain resistance which was called the threshold of resistance of the synaptic junction. From this point the stimulus passed on along another nerve fiber to another synapsis and so on until it reached the cortex of the brain. At each junction there was a resistance which served to redistribute different types of stimuli. On the way from the periphery to the cortex, the threshold of resistance became greater and greater. Alcohol had an interesting action on these thresholds in that it increased the amount of resistance encountered, therefore it excluded stimuli from getting into the human body. If enough alcohol were taken some of these synapses were cut off and the individual became more or less a desegmentated creature. This cutting off of the synapses by alcohol was accompanied by a sense of ease and the individual felt more or less at rest. He experienced a sense of comfort probably because of the lesser amount of energy that he had to handle. Dr. Clark spoke of the stimulation of alcohol, but he did not believe Dr. Clark meant that, for it was not a real stimulation but a pseudo-stimulation or a release of inhibition. The individual thus got a sense of self-confidence and protection and he could keep along with the herd. It was well known that if a man got a little above the herd he was sure to be lambasted, but alcohol by cutting off the higher inhibitions enabled a man to keep in contact with his fellows. Again a man after having taken a certain amount of alcohol dismissed timidity in his connection with the herd and felt and thought for himself and this gave him a sense of power. Alcohol, religious ecstasy, and drugs helped man to play the part of Jehovah by cutting off certain stimuli and shutting him up in his thoughts. It was true also that conventions made cowards of us all and that alcohol seemed to raise a man above himself and to give him socalled Dutch courage, but it did more than that, it drove away timidity and made him, in vino veritas, what he really wanted to be. It was well known that the members of the herd had a great tendency to so adopt a protective coloration by adopting the rules and customs of the herd that there was a great tendency to repression and to make men monotonous and like each other; they got this way to escape special notice. Alcohol by cutting into these repressions frequently lifted an individual of marked character out of this rut and frequently let him spark with his originality. It was largely because of this possibility that the herd stuck to a substance that, in spite of its possibilities for devastation, released powers of divination almost. Furthermore, it permitted a growth of sympathetic understanding, one of the necessary attributes if men would not destroy each other.

Dr. Charles L. Dana, who was to have taken part in this discussion, sent a brief letter which was read by the Secretary, expressing the opinion that absolute prohibition was an unnecessary restriction on individual liberty and a rather unwise step in the present state of social unrest.

Dr. E. E. Southard of Boston said that, as to what was going to happen when prohibition went into effect, those who read statistics wondered what the outcome would be. He thought prohibition would do some good in assisting them to make a decision in reference to mental diseases. Mental diseases were similar in males and females. In Germany, Scotland, Massachusetts, and New York, the number of beds required for both sexes

was identical. The male side was filled with alcoholics, while the female wards were filled with mental diseases due to other causes. The question that came up was whether alcoholism was actually the cause of the mental disease among these men or whether it was merely associated with some other mental disease. If this law went into effect it would settle this and several other questions. They would see whether they could not reduce the number of beds for males and have more beds for females, and then they had had their questions answered, the prohibition law might be repealed and alcohol brought back again. The prohibitionists were so strongly individualistic that they were almost the equivalent in that respect to the Bolsheviks. They were a small noisy minority, and at the present time small noisy minorities seemed to rule. This would be likely to go on unless some group system could be organized that would beat them. They had not so far been able to do this in Boston and from what he had heard they had not done so in New York. In a recent letter to the speaker Colonel Mott had expressed regret that the United States was to have prohibition and voiced the hope that the soldiers on their return would have something to say about it. Colonel Mott's opinion carried weight because he was well informed on all phases of the alcohol problem. A recent investigator had found that with chloroform one might bring out an excess of reflexes, and it was altogether possible that under the influence of alcohol something might be released in the nervous system that might be deleterious to the individual. He did not believe that we should either release or put on the inhibitions by means of alcohol. As to what had been said in regard to the threshold of resistance, the influence of alcohol might act equally in both directions and as a consequence alcohol might be paralyzing in its effect. It would seem from the arguments presented that one could prove almost anything.

Dr. H. CLIMENKO spoke of the use of alcohol by the Jewish people. He stated that they were not abstainers, but on the other hand were encouraged to use a small quantity of alcohol, yet there were no alcoholics among the Jews and the problem of insanity was not greater among these people than among others.

Dr. L. T. LE WALD asked Dr. Sherwin how he estimated the capacity of the stomach. In the paper he had spoken of estimating the normal capacity of the stomach. As a roentgenologist he had found that one of their greatest difficulties was in estimating the capacity of the stomach because the fluid passed out so rapidly, and a fluid containing alcohol ran out even faster than other liquids.

Dr. JOSEPH BYRNE said the question was a large one for him to discuss with so little notice, though perhaps he might say something about alcohol as a friend of humanity. It certainly had proved itself of great social benefit and there was not the least doubt in his mind that there were very many here tonight who had owed something at some time or other to moderate indulgence in alcohol. On the other hand, there were economic questions which legislators had overlooked when they had so hurriedly committed themselves to prohibition legislation. He had worked among the lower classes and understood their needs and he knew what a drab thing their lives were at the best. They had done the greatest part of the hard drudgery of the world and received the least compensation for their services of any class of society. He had never watched laborers at severe toil in the burning heat of summer or in the zero weather of winter without thanking God it was not his to do such heart-breaking, monotonous work. Yet he had been a thoroughly trained athlete and not at all afraid of hard physical exertion. After having done hard work of this kind these men needed something as a "set off" for their mind dwarfing occupation, and we had done a contemptible thing in his opinion to these poor people when the hand of the legislator was allowed to be turned against them. The question was an open one as to whether alcohol was the terrible thing that it was said to be and whether it did the things we sometimes heard it did. Dr. Brill had said that the prohibition movement probably represented an over-action against the too frequent use of alcohol and perhaps it did in exceptional instances. One of the greatest authorities on the Common Law in England, Sir Frederick Pollock, said it was a grave mistake to try to reform people by legislation and that those who stepped in and tried to reform people by legislation invariably in the long run did more harm than good.

Col. SHERWIN said that as to the amount of alcohol that caused intoxication and the amount that could be contained in the stomach there was no doubt that the capacity of the stomach might be increased both normally and pathologically. It was also true that liquid containing alcohol passed very quickly into the duodenum. The figures quoted, however, gave a working hypothesis.

Stated Meeting, Held October 16, 1919.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

DR. GEORGE DAVID STEWART, in introducing the speaker of the evening, said it was evident to even the most casual observer that men had lost the charts whereby they had been accustomed to direct their course in life. To-day we were not only spectators but real actors in the greatest revolution in history. What we were pleased to call the civilized world was in an emotional turmoil as great as that existing at the time of the French Revolution. Indeed, in Russia the scenes of the French Revolution were being reenacted to-day. This must give us pause. It was the destiny of man to struggle and it was his privilege to struggle, for everyone knew that when strife ceased man went down into winter. It was not the strife that was abnormal but the exacerbation of strife, such as we were now passing through, which caused men to lose their perception of perspective. We heard much of Socialism. Socialism was a beautiful dream, the only trouble with it was that it would not work. It was like a beautiful motor with all the wheels in place but without motor power. It needed altruism, as taught by Confucius and Christ, but which had never in the history of the world been a predominating characteristic of the great mass of the people. When man was ready to give up working for himself and to work for others Socialism would work, but not before. A beautiful illustration of such altruism had been given by Cardinal Mercier who stood before his arrant conquerors and dared them to do their worst. Medicine had always borne on its inscription "To the Brotherhood of Man" and that was because they were Socialists in the only way that was worth while, and it was for this reason that they had asked Dr. Stewart Paton, who had been thinking more closely along these lines than it was possible for a surgeon to do, to address them.

The Present Emotional Unrest—Its Causes and Treatment.—Dr. STEWART PATON of Princeton University delivered this address. (See MEDICAL RECORD, p. 787.)

Dr. FOSTER KENNEDY, in discussing the causes of the present emotional unrest, related that in May of last year there appeared in the *London Gazette* the announcement of the posthumous award of the Victoria Cross to an engineer-lieutenant who, in the British retirement of March 23, when a defective time fuse to a mine under one of the Somme bridges refused to act, walked back to the bridge and lighted an instantaneous fuse. Sitting here in amicable debate one might well wonder at the cool ability for such a tremendous act, yet self-sacrifice had been the daily pap of millions for nearly five years. The danger to our herd accompanying a great struggle occasioned an enormous increase in that instinct of gregariousness which was normal in man. We had been too long accustomed to class yielding to instinct with self indulgence; on the contrary the most powerful instinct in man whipped him when his kind was threatened into self immolation and destruction. Indeed it became clear to most of them during the war that those men who suffered from emotional collapse in the face of strain did so by reason of the great emotional conflict in them between their conscious duty to go forward—a desire recognized by the herd as of good repute but often making needful individual destruction—and the sub-waking instinct of self-preservation dormant in time of peace and sedulously suppressed in

time of war. The safety of the herd was guarded by the suggestibility of man; from one to the other there passed the emotional slogan which accentuated the normal nonrational thinking of each one of us, and we imposed on ourselves at the whispered command of our race the self-denying ordinances of discipline and herd loyalty. But the patriotism of the army was produced by that of the parish pump. A man was valuable to the army only by so much as he believed his regiment and his platoon to be the finest in that army. The great group was many groups fused by fear—remove that fear, and fusion was undone; in the stable minded who would always hear the voice of the herd, the intense loyalty given to the race was now given only to the class, and in those of unbalanced emotions the loosening of the hold of herd discipline would remove such inhibiting influences as in normal times forbid anarchy.

These men, swayed now by their group emotions and their egoistic passions, had seen or felt in the war the great value of direct action and violence as a method of attainment, and many of them felt through war what before they only intellectually knew "that one day they'll die." They sought to gather to their classes or to themselves what they could, in the time left to them,—and this was a world of changed values, where money, the symbol of power, had fallen more in three years than in the three preceding centuries, and where the relationship between wages and production had been destroyed by years of frenzied governmental buying. And here lay one of the immediate methods of treatment; wages for all classes must be advanced precisely in proportion to the changed value of the dollar, and to the amount of work produced, and the public must be educated to see that without increased production there could be no alleviation of their individual fortunes. The community must fight group domination by displaying its ability to dispense with the services of the group menacing it. This meant that the herd instinct of the larger group must be stimulated by an educational campaign.. It was not possible for the laboringman's muscles to replace the professional man's brain in community service, but our muscles were as good as theirs and by concerted action it could be demonstrated. Dr. Kennedy also touched on what he believed to be one other of the emotional causes of the demobilized soldier's unemployment and of the unattainable programs of Labor: they were due largely to an inherently wrong attitude on the part of the public in wartime towards labor and towards those of us who went to the war—a sentimental adulation which swelled all our heads and blinded us to the fact that in France and in the dockyards we were simply repaying a lifelong debt to our country, not putting our country in debt to us. Why should we sentimentalize over a man obeying his normal instinct to defend his race? Men should go to war as naturally as women bore children! The paternalism of governments and the general public towards the armies of soldiers and laborers had been calculated to produce many spoiled children.

Dr. Frederick Tilney raised the question as to whether social unrest was pathological or biological. Was it a disease for which we sought a cure or an insurgent energy which we must learn to direct. Experience and history provided abundant material so that this question might be submitted to scientific analysis. If we turned to history we should find: (1) the fires of the Renaissance were already waning when the spirit of social unrest infected a group of men and women overseas. They crossed the ocean, came to a new land, and made the readjustment which allayed their unrest. (2) Several generations later we saw their children in mortal conflict seeking a new adjustment—that was the Revolution. A happy and pacific people only a little more than a half century ago emerged from one of the most sanguinary conflicts in which they sought the right to adjust a great difficulty. (3) Finally, and still within our experience, we found ourselves giving and ready to give all that we were to stand in the culminating catastrophe of war. Eighteen destructive wars had occurred during the past twenty-five years, and we asked what peculiar kink had gotten into the psychology of laundrymen and miners, steel workers and Bolsheviki, making them willing to exchange peaceful living for strife and discontent. Personally, he believed that strife was the heritage of primitive man. He passed it on through countless generations just as it was handed on to him from countless ages before. Social unrest was born of the spirit seeking readjustment. Its product was not always so satisfactory as in our own history, for the unrest of the social fanatic as well as the lover of liberty, must have its expression. In saying that unrest and even strife were natural and biological, he did not mean that they were never harmful. In that they were not constructive they were inefficient; in that they were destructive they were wasteful. If we were to avoid these charges against our civilization, we must direct this unrest energy aright. The question was where to begin and how to proceed. Undoubtedly it was a question of proper personality adjustment. First, individual personality, then national personality, and after that international adjustment was sure to come. Yet how little we understood of personality—our own, for example.

Let it be said by way of introduction that personality depended on the brain. How little we knew about this organ, and how rather proudly most of us admitted it. How little we understood the mechanism of the essential emotions—of fear, of hate, of anger, of self-abasement and self-assertion, of parental instinct, of the instinct of pugnacity, and many other general innate tendencies; to say nothing of the nature of sentiments, the growth of self-consciousness, and the development of volition. We had schools which gave instruction in everything under the sun except about ourselves in the more vital sense. But where was the school that taught the significance and opportunities of motherhood, the duties and privileges of good citizenship, or the relations of the individual to society?

In many cases such an education as we did provide became an actual liability, an encouragement to license and not an incentive to intelligence. In the greatest city in the world we had a Board of Education which did not contain a single recognized authority on education. This defect you might discount on the ground that it was other people's children who were being educated through our public schools; but it was to be borne in mind that it was just these children whose defects in personality and intelligence were to determine the welfare or disaster of our future. As a profession education was ridiculously underpaid. Its emoluments were not sufficient to attract or retain the services of the best minds in our country. It would be impossible ever to understand ourselves or our opportunities until the teaching profession was lifted, not to a higher, but to the highest plane possible. In the agency upon which we depended most for our stability, namely, education, we were at present making a niggardly investment. It was only as we expanded and broadened the means by which we might understand ourselves and our relations to others, by which we should cause a cessation of the present alleged hierarchy of intelligence, and we should learn to direct the present insurgent energy of unrest. Dr. Tilney expressed the view that the present unrest was not the recrudescence of old disorder or the eruption of a new epidemic, and that there was no specific that would effect a cure. The process was long and tedious. The first step was the recognition of the defects in ourselves and our social organization. The second was the determination to see them corrected. Achievement was a long way off, but even though we were still in the morning time of the race, there was light enough to see the way.

Dr. Thomas L. Darlington expressed himself as most optimistic, first of all because they were having a discussion of this kind, something they had never done before in this way. He said he happened to be one of those who lived during and after the other "unpleasantness," and the same problems came up as persistently as they were now doing. At Gettysburg, fifty years afterward, the old soldiers were telling of the things they did in the war and of many things they had not done, but had come to think they had done, and many of them had never done anything since the Civil War. They served as examples of the ego reinforced tremendously. But that was what happened after all wars.

We were creatures of habit and war ruptured all the habits of life and all its relationships in a moment, and of course there was a disturbance. He was glad to see Dr. Paton's first headlines under the evidences of sanity, "Joy in living and pleasure in work." If we ever got back to normal conditions it was going to be by increased production. That was the lesson to be taught the world. We were made in the image of the Creator and He took the greatest pleasure in the things He did. In work lay the remedy for the present unrest. We must get back to work and increased production and then the people would forget about other people's troubles and would think of their own. He was glad Dr. Paton spoke of the importance of the muscular system. Muscular contractions caused the blood to circulate more rapidly carrying it from the brain and vital organs to the muscles with the result that sleeplessness and indigestion were relieved. One of the greatest troubles at the present time was that the people were not in good physical condition.

As physicians they had not done their duty by the people. They had not taught the people the simple things of life, to wash their hands and use a toothbrush, and yet for thirty years they had known about infection. That was what they were trying to do in the steel industry, but when they had to deal with people speaking twenty-four different languages and unable to read, it was a difficult problem. They had been talking about sanitation. There were nearly five millions of people who went through our hospitals every year, yet these people were not taught the simple rules of hygiene. Something more should be done for them than simply operating or giving drugs; they should be taught the rules of right living. If the people were getting proper food and eating and sleeping well it would be a factor in allaying social unrest. If one would go back to the Hittite civilization, six thousand years ago, he would find things written there about the condition of the world at that time and laments that "the times were not what they used to be." We had the same old problems today that they had at that time and we must face the situation squarely as physicians, for many of the problems could only be solved by physicians; if we were united we could take care of them in our own way.

Mr. Homer A. Dunn said that there were forces that could be brought to operate for the cure of evils. As examples of such forces he called attention to the work of Vigilantes in California and to forces in the Middle West which cured cattle and horse stealing. We were apt to think that the hanging of a horse-thief was wrong, but it must be remembered that the horse-thief was a direct menace to the lives of women and children, since horses were scarce, and the family was dependent upon them. The forces at work today were the result of accumulated effort to get into the other man's place too rapidly, and they were treading on the ground to which Dr. Paton referred when he spoke of them as trying to adjust themselves above their plane. The question was how to reach and make people realize the actual facts as they were. Any one in control of large groups of men could not help but see the yeast working, men trying to get above their level and resorting to all kinds of means to accomplish their end, to illegal procedures and camouflage. Whether the causes of this condition or disease were psychological or biological it was important to get the psychological part before the people. It was not nearly so important to get it before an audience like this as before the kind of an audience one would get at Cooper Union, and not only in New York City but in all the large cities, for the same conditions were found in all large cities, the only difference being the difference in intensity depending upon the number of people. The psychology of social unrest should be given to the people in plain language that they could understand, and to do this it would be a good idea to write on a blackboard, where such a lecture was to be given and where the people would see it, the definitions of words such as "biology," "psychology," and other more or less technical words that were necessary to use in presenting the facts, so that the people might become familiar with them and be prepared to understand the subject when it was presented.

Miscellany.

Metapsychics.—Under this name Chauvet in the *Gazette des hôpitaux* for July 3 refers to various borderline phenomena, the study of which may be kept within the bounds of subconscious activities. Another term used is psychodynamics. The phenomena of hypnotism and hysteria belong under metapsychics, and the main difficulty is to determine the superior limitation of such activities. The author's article is essentially a review of a work by Geley on the "unconscious and conscious," just published. By the unconscious may be explained to the satisfaction of many, such phenomena as the divining rod, telepathy, presentiments, etc. In France Professor Richet is the leader of a movement which is apparently identical with that of the British Society for Psychical Research. Among the founding members are Geley, the author of the work under review, Teissier, Flammarion, and others well known. A periodical has been established, the *Journal des Sciences Psychiques*. The investigations by the society are not to be conducted along narrow paths; rather, all science is to be focussed on this one subject. Metapsychics, in other words, must run the gauntlet of all the sciences. For example, the author's belief in evolution is checked up by a counter-belief that it has only a certain limited scope in the scheme of creation. He sees in insect metamorphosis a dematerialization. Histolysis destroys the embryo while the future insect is regenerated or rematerialized and has absolutely no continuity with its predecessor. The medium of the highest class, he explains as a product of evolution from the ordinary "cryptomnesic" and "cryptopsychic," which latter are both within the province of psychophysiology. There is a psychism which is above all organic phenomena. This is also responsible for consciousness and personality. In the ordinary individual, psychodynamic manifestations are latent—hence the use of the words cryptomnesic and cryptopsychic. Superpsychism, on the other hand, is responsible for all genius and inspiration or intuition.

Death of Lecha-Marzo.—The distinguished young professor of Forensic Medicine in the University of Seville died quite recently at the early age of 31. He was born in the Island of Luzon in the Philippines and began the study of medicine in Valladolid, under his uncle Luis Lecha-Martinez, who held the local chair of Legal Medicine. He was then but 16 years of age, so that despite his short life he spent fifteen years at his special work; and from the very outset of his career made important discoveries. At the age of 19 he published a remarkable monograph on the semen. In his choice of subjects he was actuated entirely by forensic values. Some microscopic work on the cortex was honored by Ramon y Cajal with a preface and annotations. Next he took up scientific detective work and published a study of the hand of the insane and criminal. There followed a treatise on autopsies and embalming and finally his mammoth work on legal medicine, but one out of a series of volumes having appeared at the time of his death. The deceased was clearly a prodigy and doubtless attempted too much, for his efforts were those of an average lifetime.

A YEAR OF PROTEAL THERAPY.

BY HENRY SMITH WILLIAMS, M.D.

NEW YORK.

WHAT are the applications and limitations of nonspecific protein therapy?

Doubtless that is one of the most important questions before the medical profession to-day. A partial answer to the question was attempted in my book, "The Proteomorphic Theory and the New Medicine," issued about May 1, 1918. It may be of historical interest to recall that a considerable part of the matter in this book was reproduced unchanged from an exposition of the Proteomorphic Theory published as long ago as October, 1914. Another section of the book, dealing chiefly with cancer, was largely the reproduction of a Monograph published in December, 1916. The major part of the newer matter, theretofore unpublished, dealing with the applications of nonspecific protein therapy to a variety of conditions of disturbed metabolism, including arthritis, anemias, intestinal toxemia, asthma, psoriasis, and tuberculosis, was originally written prior to April, 1917, but bore amendations and additions bringing the subject down to the date of actual sending of the manuscript to the printer; the last of such additions being made about March 4, 1918, the date originally set for the publication of the book.

The present paper may be regarded as a condensed summary of my experience with protein therapy in the intervening period. In the interest of clearness, it may be necessary now and again to repeat or reiterate matters of theory or practical observations dealt with in the book; but this will be done only exceptionally and with all practical brevity.

It must here suffice, for example, to say that the protein response—to which more than one hundred pages of the book are devoted—is manifested in the activation of the blood-forming mechanism and of the enzymic properties of the blood corpuscles themselves. According to the proteomorphic theory, the white corpuscles begin the decompounding of all foreign proteins in the blood stream, and the red corpuscles complete this decompounding. This theory ascribes to the corpuscles, and in particular to the red corpuscles, a share in bodily metabolism hitherto unsuspected.

The observed blood modifications that follow the administration of nonspecific proteins are such as to give strong support to the proteomorphic theory. If handling of foreign proteins is a function of the corpuscles, the modification of the corpuscles in response to the invasion of a foreign protein (as from the hypodermic injection of any protein) must be a fundamental organic response, analogous to the increase of specific antibodies following a bacterial invasion.

Recognition of this fundamental fact is essential to an understanding of the observed results of the therapeutic application of the nonspecific proteins.

Proteals and Other Proteantigens.—Most readers are probably aware that the word proteal was suggested by me as a convenient name by which to designate vegetable proteins prepared for hypodermic administration. The word has not been applied, so far as I know, to protein extracts made elsewhere than in my own private laboratory; but it is applicable—if accepted by the profession—to all vegetable-protein extracts, wherever or however prepared, being intended as a generic term to stand on a par with the familiar terms serum and vaccine.

It may be of interest to note that I have suggested the word *proteil* to designate animal proteins of any type used as therapeutic antigens; and the still more comprehensive word *proteantigen* as a convenient family name for all proteins used as antigens, including serums, vaccines, proteils, and proteals. That these words supply actual needs in our nomenclature will, I think, be obvious.

I have personally brought the proteals, and the method of their preparation, to the attention of several promiment pharmaceutical houses; the secretaries of all prominent medical societies; and the Boards of Health of all our States and of all cities of over ten thousand inhabitants in the United States. I have repeatedly expressed, and I herewith reiterate, the belief and expectation that proteals will presently be prepared in Board of Health and hospital laboratories everywhere, as certain serums and vaccines are now made, for free distribution to the profession for treatment of the poor. Meantime the resources of my small private laboratory, which is merely a department of my office, have been placed at the disposal of government, State, and private institutions everywhere, and I have welcomed the cooperation of members of the profession in private practise. In at least two instances groups of patients numbering more than fifty have been under protracted treatment in official institutions with proteals supplied gratuitously from my laboratory; and some scores of smaller groups in hosiptals and sanitariums, together with hundreds of cases under observation of physicians in private practise in various parts of the country, have given opportunity for the acquisition of a body of information regarding the applications and limitations of proteal therapy of notable interest.

That this experience aggregates really respectable proportions will be evident when I state that the quantity of proteals sent from my laboratory during the past three years in response to requests from institutions and individual practitioners (shipment being made in ampules varying from one mil to twenty-five mils) aggregates about a quarter of a million average doses. As the proteals are usually administered three times a week, this represents two months' treatment for about ten thousand cases. Informal reports regarding a considerable proportion of these cases have come to me from time to time, supplying valuable data of the most practical character to supplement my direct personal observations.

The nonspecific vegetable proteins, or proteals, referred to throughout are prepared in my private laboratory from seeds of various kinds—alfalfa, millet, rape, mustard, etc.—by a simple method of boiling with dilute hydrochloric acid, which partially hydrolyzes the proteins; filtration; neutralization with sodium hydroxide; standardization by the Kjeldahl nitrogen test, on the basis of three milligrams of nitrogen to the cubic centimeter (approximately a two per cent protein solution); and, after sealing in ampules of various sizes, sterilization by the discontinuous method. The working formula for this method of preparing the proteals has been repeatedly published, and is of course available for use in any laboratory, private, institutional, or commercial.

To what extent the method is employed by pharmaceutical houses preparing nonspecific vegetable proteins, I am not informed, as I have no association, direct or indirect, with any institution or individual having to do with the preparation of such extracts.

Various other methods of extracting the vegetable proteins are described in my book, but the method just outlined has the advantage of expeditiousness and the far more important advantage that the extract thus prepared may be freely used (administration being of course hypodermic) without fear of anaphylaxis, which must always be considered when the unbroken proteins are employed. The production of a marked therapeutic response without the slightest appearance of local or general anaphylaxis, the patient being subjected to no discomfort whatever, is one of the most striking and gratifying characteristics of proteal therapy, as now under consideration.

The Types of Proteals.—No specific names have been given the different proteals, but it has been found expedient, in laboratory use, to designate each extract or combination of extracts with a number.

The numbers given the various individual protein extracts hitherto employed are as follows: No. 29, extracted from Alfalfa meal; No. 36, extracted from Mustard seed; No. 38, from Millet seed; No. 39, from Alfalfa seed; No. 42, from Rape seed; No. 50, from Oats; No. 61, from the Potato tuber; No. 62, from Wheat; No. 63, from Carrot seed; No. 64, from Flaxseed; No. 66, from Cottonseed; No. 67, from Red Cloverseed; No. 68, from White Clover seed; No. 70, from Spinach seed. Of these No. 39, Alfalfa seed protein, is used much more extensively than any other single one, as statistics of case reports will show. For convenience in administering larger doses, a double-strength (four percent) solution of alfalfa seed protein is made, and this is designated 39-A. Similar double-strength extracts are made from a few other seeds. These are similarly designated with an "A" but in general the 2 per cent. protein solution has been found more convenient.

The combinations of proteins most employed, with their laboratory numbers, are the following: No. 37, equal parts of the proteins of Mustard and Alfalfa seeds; No. 40, equal parts of Mustard and Rape seed proteins; No. 45, equal parts of the proteins of Alfalfa seed, Alfalfa meal, and Millet seed; No. 60, equal parts of the proteins of Alfalfa seed and Alfalfa meal; No. 65, equal parts of the proteins of Alfalfa meal and of the seed proteins of Alfalfa, Mustard, Millet, and Rape; No. 75, equal parts of the seed proteins of Red Clover, Cotton, Hemp, Flax, and Carrot; No. 80, equal parts of the seed proteins of Alfalfa, Millet, Rape, and Mustard; No. 100, equal parts of the proteins of Alfalfa meal and the seed proteins of Alfalfa, Millet, Mustard, Rape, Red Clover, Cotton, Hemp, Flax, and Carrot.

It will be observed that Proteal No. 65 combines five types of proteins; that No. 75 combines five other types of proteins; and that No. 100 is made by combining numbers 65 and 75. In the condensed report that follows, it will be convenient to conserve space by using numbers, avoiding the cumbersome repetition of names. The numbers that will recur constantly in the ensuing report are 39, 45, 65, 75, 80, and 100.

I do not know that I can better illustrate the wide range of pathological conditions to which proteal therapy has been found applicable than by giving a condensed summary of a consecutive series of recent and (with two or three exceptions) hitherto unpublished cases from my office files, presented in the order of their first visits, and therefore quite unselected.

This group of unselected cases represents a consecutive series limited to 100 merely for convenience. The number is not large enough, perhaps, for elaborate statistical purposes, but it suffices to give at least a general idea of the types of cases thought suitable for proteal treatment in my office. Dealing with a group of 100 cases, percentages are obviously the same as numbers; it may therefore be of interest to note that in this group there are 15 cases listed with intestinal toxemia as the chief diagnosis; 20 cases of neurasthenia; 18 cases of tuberculosis; 18 cases of thyroid disturbances; the remaining 29 cases representing conditions of disturbed metabolism having a variety of pathological sequels—arthritis or diabetes or nephritis or psoriasis or bronchial asthma or epilepsy or psychoneuroses (various and sundry) according to the inherent susceptibilities or the environmental influences of the different subjects.

I insist not at all on holding to rigid diagnostic boundaries in this analysis. I have merely endeavored in each case to note what seem the predominant symptoms or pathological conditions at the moment. It goes without saying that the groups merge, and that any number of cases might with propriety be classed in other groups than those in which they

A New Series of 100 Original Cases Under Proteal Treatment.

Administration, always deep subcutaneous; usually three times a week, but sometimes daily, notably in malignant cases. Initial dose, always ɱiii to ɱv, increased minim by minim or much more rapidly, according to urgency or severity of the case.)

Case No.	Name.	Principal Malady or Pathological Condition. (With Comment as to Associated Conditions or Symptoms.)	Proteal Treatment: Types of Proteals Administered; Maximum Dosage; Duration of Treatment.	Progress of Case—Chiefly with Reference to Clinical Progress. Blood Conditions Detailed in Subsequent Tables.
2384	Mrs. W.	Intestinal toxemia; hypnadrenia; anemia, nausea, dizziness, prostration.	Nos. 42, 39, 39-A, 100; max. dose ɱxii of 39-A; 30 mos., wit intermission.	Metamorphosis in blood conditions; complete clinical recovery.
2385	Mr. E.	Pulmonary tuberculosis; typical syndrome; extreme cachexia.	Nos. 45, 42, 65, 39, 75, 80, 39-A; max. dose, ɱxxv; 26 mos., with intermission.	Conspicuous blood modification; greatly decreased cachexia; marked clinical improvement.
2386	Miss M.	Neurasthenia; hypertension, with typical syndrome.	Nos. 45, 40, 39, 65, 100, 39; max. dose, ɱx; 26 mos., with intermission.	Quick response; lowered blood pressure; marked clinical improvement.
2387	Mr. M.	Pulmonary tuberculosis; typical syndrome; hemoptysis.	Nos. 42, 60, 45; max. dose, ɱx; 24 treatments.	Greatly improved blood conditions; striking clinical improvement.
2388	Mr. H.	Lymphatic leukemia; fairly typical syndrome, with parotic tumors; multiple glandular nodules; leucocytes more than 1,000,000.	Nos. 60, 45, 42; max. dose, ɱviii; 4 mos.	Striking regression of glandular enlargements; temporary clinical improvement; subsequent history unknown.
2389	Mrs. K.	Pulmonary tuberculosis; typical syndrome including hemorrhage; moderate goitre; albuminuria.	Nos. 39, 60, 45, 65, 45, 39, 75, 39, 45, 75, 80, 39-A, 75, 100; max. dose, ɱxxiv; 18 mos.	Conspicuous blood modifications; great reduction in goitre; striking clinical progress, fairly rapid and cumulative; treated only occasionally in past 6 mos.
2390	Dr. S.	Chronic nephritis hypertension (210-140) retinal hemorrhage; neurotoxic syndrome.	No. 39; max. dose, ɱviii; 11 treatments.	Clinical syndrome favorably modified, but under stress of excessive work, the patient collapsed and developed uremic poisoning, with fatal termination 10 days later.
2391	Mrs. B.	Intestinal toxemia; duodenal ulcer suspected.	Nos. 42, 39; max. dose, ɱviii; 11 weeks.	Apparent clinical recovery.
2392	Mr. B.	Neurasthenia; specific origin probable.	No. 39; treatment continued by home physician.	Final results not reported.
2393	Mr. D.	Neurasthenia; mitral insufficiency.	Nos. 42, 65, 39; max. dose, ɱx; 12 mos., with intermission.	Pronounced clinical improvement.
2394	Mrs. V.	Dysthyroidism; typical syndrome.	Nos. 39, 65, 39, 80, 42; max. dose, ɱviii; 12 mos., with intermission.	Apparent restoration to normal.
2395	Miss O.	Bronchial asthma; probable tuberculous complication.	Nos. 45, 42, 39; max. dose, ɱx; 15 treatments.	Modification of character and period of attacks; no permanent improvement.
2396	Miss K.	Pulmonary tuberculosis; typical chronic case.	Nos. 39, 65; max. dose, ɱviii; desultory treatment.	Moderate improvement; doubtful prognosis.
2397	Miss G.	Pulmonary tuberculosis; late stage.	No. 30; max. dose, ɱvii; treatment for brief period only.	Death reported 10 mos. later.
2398	Mrs. S.	Pulmonary tuberculosis; late stage; previous tuberculin treatment.	Nos. 65, 39, 45, 75, 45, 80, 39, 39-A, 75, 100; max. dose, ɱxxv; 20 mos.	Marked improvement for a time; regression and fatal termination.
2399	Mrs. D.	Intestinal toxemia; enlarged cervical glands.	Nos. 42, 65, 39, 75, 43, 80, 39-A, 42; max. dose, ɱxii; 8 mos.	Disappearance of glands; clinical recovery.
2400	Miss A.	Neurasthenia; tuberculosis feared.	Nos. 42, 39; max. dose, ɱviii; 8 mos., with intermission.	Very satisfactory progress.
2401	Mrs. D.	Neurasthenia; hypertension; anemic obesity.	Nos. 42, 39, 65, 42; ax. dose, ɱx; 6 mos., with intermission.	Highly gratifying response, prompt and cumulative.
2402	Mrs. R.	Intestinal toxemia; pronounced psychoneurosis.	Nos. 42, 39, 75; max. dose, ɱx; 17 weeks.	Marked clinical improvement.
2403	Mr. A.	Psoriasis; general health much impaired	Nos. 65, 39, 45, 40, 65, 39-A, 44; max. dose, ɱxxiv; 7 mos.	General health greatly improved; psoriasis stationary but subsequently yielded to local treatment.
2404	Miss K.	Hyperthyroidism; arthritis; probable postpituitary insufficiency.	Nos. 65, 80, 39, 39 and 80, 65, 75; max. dose, ɱxv; 14 mos., with intermission.	Satisfactory progress in all respects.
2405	Miss N.	Pulmonary tuberculosis, far advanced.	Nos. 42, 39; max. dose, ɱxiv; 15 treatments.	No marked change; reported in fair condition 15 mos. later.
2406	Mrs. T.	Progressive arthritis; local infection in tonsils.	Nos. 39, 45, 65, 39-A; max. dose, ɱxx; desultory treatment for several months.	No improvement until tonsillectomy

A New Series of 100 Original Cases Under Proteal Treatment—(*Continued*)

(Administration, always deep subcutaneous; usually three times a week, but sometimes daily, notably in malignant cases. Initial dose, always ɱiii to ɱv, increased minim by minim or much more rapidly, according to urgency or severity of the case.)

Case No.	Name.	Principal Malady or Pathological Condition. (With Comment as to Associated Conditions or Symptoms.)	Proteal Treatment: Types of Proteals Administered; Maximum Dosage; Duration of Treatment.	Progress of Case—Chiefly with Reference to Clinical Progress. Blood Conditions Detailed in Subsequent Tables.
2407	Mr. S.	Chronic arthritis; hand crippled. Incapacitated for work.	Nos. 65, 39, 36, 39-A; max. dose, ɱx; 2 mos. regularly, with 14 additional treatments at lengthened intervals.	Complete recovery; no recurrence within 8 mos.
2408	Mr. G.	Duodenal ulcer; x-rayed; diagnosis not definitive.	Nos. 65, 39; max. dose, ɱviii; 15 treatments.	Marked improvement; in good condition at last report.
2409	Mrs. T.	Chronic arthritis; of long standing and exceedingly resistant.	Nos. 65, 39, 39-A, 80, 75, 100, 100 and 44, 44 and 69, 39, 65; max. dose, ɱxxv; 13 mos., with intermission.	Marked improvement; favorable prognosis after removal of focal infection in teeth.
2410	Mrs. V.	Carcinoma of breast; postoperative; radiumed; hopelessly advanced.	Nos. 39-A, 75, 100, 100 and 39-A, 45, 45 and 41, 44 and 69, 80 and 66, etc.; max. dose, ɱxxxv; 14 mos.	Life seemingly prolonged with comfort for 14 mos.
2411	Miss G.	Neurasthenia; endocrine disturbance; probable hypoadrenia.	Nos. 65, 39; max. dose, ɱviii; 18 treatments.	Variable and not permanent improvement.
2412	Mrs. K.	Chronic arthritis; psoriasis.	Nos. 65, 80; max. dose, ɱviii; 11 treatments only.	Eruption modified; treatment too brief to expect marked results.
2413	Mr. T.	Pulmonary tuberculosis; static condition.	Nos. 42, 39; treated by home physician.	Apparently favorable progress at last report.
2414	Mr. A.	Psoriasis; obstinate case of long standing.	Nos. 65, 80, 45; max. dose, ɱxv; 3 mos.	Spectacular recovery under proteal treatment exclusively; reported well 9 mos. later.
2415	Mr. K.	Pulmonary tuberculosis; chronic, moderately rapid development; several hemorrhages.	Nos. 65, 39, 80, 39-A, 75, 100 and 44, 45, 44 and 69, 80; max. dose, ɱxxx; 14 mos.	Apparent progress for 15 mos.; prognosis hopeful.
2416	Miss A.	Dysthyroidism; extreme anemia; positive response to tuberculin test.	Nos. 65, 39; max. dose, ɱxii; about 2 mos.	Rapid progress and apparent complete restoration.
2417	Miss L.	Pulmonary tuberculosis; early stage; complicated by goitre.	Nos. 80, 39, 39-A, 75, 80, 39-A, 39-A and 100, 100, 80; max. dose, ɱxxx; 13 mos.	Satisfactory progress in all respects; good prognosis.
2418	Mrs. M.	Intestinal toxemia; tendency to anemic obesity.	Nos. 65, 80, 39-A, 80; max. dose, ɱxvi; 13 mos.; with intermission.	Prompt response and apparent complete restoration.
2419	Mrs. H.	Carcinoma of liver; late stage; general involvement.	Nos. 45, 39-A; max. dose, ɱxx; desultory treatment about 6 mos.	Marked palliation, with probable prolongation of life.
2420	Mrs. V.	Hyperthyroidism; rheumatoid complications exceptionally marked.	Nos. 65, 39, 39-A, 80, 44, 75, 100; max dose, ɱxx; 13 mos. at varying intervals.	Intermittent but pronounced and cumulative progress.
2421	Mr. D.	Dysthyroidism; hypertension with characteristic syndrome.	No. 65; max. dose, ɱxii; intermittent treatment.	Emphatic and persistent favorable response.
2422	Mr. L.	Neurasthenia; pronounced anemia; arthritis.	No. 39; max. dose ɱvi; 13 treatments.	Improved general health; disappearance of rheumatoid symptoms; normalization of blood.
2423	Mrs. M.	Nocturnal epilepsy; marked anemia and general debility.	Nos. 42, 80, 39-A, 75, 39; max. dose, ɱxvi; 13 mos., with intermission.	General improvement; lengthened interval between seizures.
2424	Mrs. B.	Pulmonary tuberculosis; chronic but relatively static case.	Nos. 45, 39, 80; treatment chiefly away from office.	Conspicuous general improvement; reports continued progress.
2425	Miss C.	Neurasthenia; frequent and striking disturbances suggestive of petit mal.	Nos. 80, 39, 39-A max. dose, ɱxvi; 7 mos.	Improvement for some months, then apparent stasis; treatment discontinued.
2426	Mrs. H.	Hyperthyroidism; pronounced goitre involving both lobes.	Nos. 42, 65, 39 (supplemented with antithyroid serum), 60, 65, 75, 39-A, 80; max. dose, ɱxvi; 15 mos., with intermission.	Regression of goiter; restoration of normal functions.
2427	Mr. A.	Neurasthenia; extreme emaciation; carcinoma feared.	No. 80, ɱvi.	Only 4 treatments no result.
2428	Dr. K.	Osteosarcoma; diagnosis never satisfactory.	Nos. 45, 39, 100; max. dose, ɱxxv; treatment intermittent for many months.	Benefited by proteal treatment, but died of an intercurrent acute malady.
2429	Mrs. F.	Hyperthyroidism; typical syndrome; moderate in character	No. 39, ɱvi to xii at varying intervals for 8 mos.	Regression of goiter; restoration to apparent normality.
2430	Mr. S.	Diabetes mellitus; typical syndrome, with emphasis on mental symptoms.	Nos. 42, 80, 39-A; max. dose, ɱxvi; 21 weeks.	Disappearance of glycosuria; apparently complete bodily and mental restoration.

A New Series of 100 Original Cases Under Proteal Treatment—(*Continued*).

(Administration, always deep subcutaneous; usually three times a week, but sometimes daily, notably in malignant cases. Initial dose, always mjiii to mjv, increased minim by minim or much more rapidly, according to urgency or severity of the case.)

Case No.	Name.	Principal Malady or Pathological Condition. (With Comment as to Associated Conditions or Symptoms.	Proteal Treatment: Types of Proteals Administered; Maximum Dosage; Duration of Treatment.	Progress of Case—Chiefly with Reference to Clinical Progress. Blood Conditions Detailed in Subsequent Tables.
2431	Mr. M.	Duodenal ulcer; diagnosis made with r-ray, but open to question.	Nos. 42, 39, 39-A; max. dose, mjxiv; 6 mos. at lengthening intervals.	Complete restoration to robust health.
2432	Dr. B.	Subacute arthritis; joints at knee chiefly involved.	No. 39; max. dose, mjxxv; about 3 weeks.	Complete recovery.
2433	Dr. B.	Neurasthenia; pronounced anemia; persistent cephalalgia.	Nos. 42, 80, 39; max. dose, mjxxv; intermittently for several mos.	Case complicated by mastoid infection; apparent marked benefits from proteals before and after operation.
2434	Mrs. P.	Albuminuria; asthenic condition following acute attack; hypertension.	Nos. 80, 39, 39-A, 75; max. dose, mjx; 6 mos., at varying intervals.	Normalized blood pressure; disappearance of albumin; apparent complete restoration.
2435	Dr. S.	Chronic arthritis; deformative involvement of wrist and fingers.	No. 39; max. dose, mjxv; 6 weeks.	No apparent improvement; treatment discontinued.
2436	Miss M.	Incipient tuberculosis, pronounced anemia and asthenia.	Nos. 80, 39, 39-A, 100; max. dose, mjxvi; 6 mos.	Blood conditions normalized; weight increased 95 to 112 lbs.; apparent complete restoration to health.
2437	Mrs. N.	Intestinal toxemia; endocrine disturbance; probable hypoadrenia.	Nos. 80, 39; max. dose, mjx; 16 treatments.	Marked improvement in blood and in general clinical conditions.
2438	Mrs. W.	Chronic nephritis; hypertension (200-128) with typical syndrome.	No. 80; max. dose, mjvi; 9 treatments. Treatment continued at home.	Prompt response and marked clinical improvement.
2439	Mr. D.	Hyperthyroidism; conspicuous neuropathic symptoms.	Nos. 80, 39, 75, 100; max. dose, mjxx; 12 mos., at intervals.	Marked improvement in general condition; amelioration of nervous symptoms.
2440	Miss W.	Intestinal toxemia; anemia, neurasthenia.	Nos. 80, 39, 100; max. dose, mjxv; 6 mos., at intervals.	Restoration to apparent normality.
2441	Miss H.	Intestinal toxemia; recent operation for gallstones.	Nos. 65, 80, 39, 39-A, 100, 75; max. dose, mjx; 12 mos., with intermissions.	Prompt and gratifying response to proteal treatment.
2442	Mrs. B.	Neurasthenia; anemia; probable endocrine disturbance.	Nos. 42, 39, 42; max. dose, mjxxv; at intervals for 8 mos.	Improved blood conditions and marked clinical progress.
2443	Mr. S.	Neurasthenia; no tangible localized malady involved.	Nos. 42, 80; max. dose, mjxx; several weeks at varying intervals.	Improved blood conditions; enhanced sense of well being.
2444	Miss T.	Hyperthyroidism; typical syndrome, with visible goitre.	Nos. 80 (following antithyroid serum), 39; max. dose, mjviii; treatment continued by home physician.	Regression of goitre; marked improvement in general condition amounting to clinical recovery.
2445	Mrs. S.	Inoperable carcinoma of the cervix in advanced stage; practically hopeless prognosis.	Nos. 39, 39-A; max. dose, mjxxv of No. 39-A; 18 treatments.	Palliation of the symptoms and temporary improvement of general health.
2446	Mr. B.	Hyperthyroidism; dyspituitarism.	Nos. 80, 39, 39-A, 75, 100, 39; max. dose, mjxvi; 13 mos., at lengthening intervals.	Marked and persistent improvement in physical and mental condition.
2447	Mr. M.	Neurasthenia; hypertension; rheumatism.	Nos. 39, 39-A, 42, 100, 80, 75; max. dose, mjxiv; 9 mos., with lengthened intervals.	General improvement; disappearance of rheumatoid symptoms; lowered blood pressure.
2448	Miss H.	Neurasthenia; anemia; susceptibility to infection.	Nos. 80, 39-A; max. dose, mjxvii; 8 weeks.	Greatly improved blood conditions and general health.
2449	Mrs. K.	Indolent ulcer on left leg; no local treatment.	Nos. 39, 39-A; max. dose, mjxv of 39-A; 14 weeks at lengthened intervals.	Lesion healed rather rapidly and completely; a mild phlebitis above the region subsided, leaving normal conditions.
2450	Mr. M.	Intestinal toxemia; neuropathic syndrome; marked depression.	No. 80; mjiii to x; 8 treatments only.	Physical and mental improvement.
2451	Miss D.	Dementia praecox; anemia formerly tuberculous.	Nos. 39, 39-A; max. dose, mjviii of 39-A; desultory treatment for 14 weeks.	Improved general physical condition and at least temporary palliation of mental symptoms.
2452	Miss R.	Neurasthenia; mild secondary anemia.	No. 80; small doses administered by nurse.	Patient left city soon after beginning treatment intending to continue, but progress has not been reported.
2453	Mr. B.	Dyathyroidism; brachial neuritis.	Nos. 39, 39-A, 100, 100 and 39-A, 80; max. dose, mjxvi; 8 mos., at varying intervals.	Definite and persistent improvement of localized symptoms and general conditions.

A New Series of 100 Original Cases Under Proteal Treatment—(*Continued*).

(Administration, always deep subcutaneous; usually three times a week, but sometimes daily, notably in malignant cases. Initial dose, always mjiii to mjv, increased minim by minim or much more rapidly, according to urgency or severity of the case.)

Case No.	Name.	Principal Malady or Pathological Condition. With Comment as to Associated Conditions or Symptoms.	Proteal Treatment: Types of Proteals Administered; Maximum Dosage; Duration of Treatment.	Progress of Case—Chiefly with Reference to Clinical Progress. Blood Conditions Detailed in Subsequent Tables.
2454	Mr. C.	Neurasthenia; mild case, typical syndrome.	No. 39; max. dose, mjviii; 7 weeks.	Marked and satisfactory response.
2455	Mr. R.	Chronic arthritis; involving shoulder joints and brachial nerves.	No. 39, 39-A, 80; max. dose, mjxvi; 9 weeks.	Gradual but satisfactory and cumulative improvement.
2456	Mr. M.	Epilepsy; frequent and violent seizures.	Nos. 80, 39, 39-A; max. dose, mjxvi; 12 weeks.	No persistent results.
2457	Dr. J.	Pulmonary tuberculosis; early stage; slight but unequivocal involvement.	Nos. 39, 80; treatment away from the office.	Prompt improvement, with apparent clinical recovery.
2458	Mr. B.	Pulmonary tuberculosis; chronic case, gastric complications.	Nos. 39, 39-A, 39-A and 44, 39-A and 80, 80 and 75, 75, 39; max. dose, mjxxx; 7 mos.	Conspicuous improvement in all respects; prognosis good.
2459	Miss S.	Carcinoma of breast; post-operative; inoperable.	Nos. 39-A, 39 and 100, 39-A, 39-A and 100, 100 and 44, 75; 7 mos.; max. dose, 3 mils.	Unequivocal palliation of symptoms, but prognosis is highly unfavorable.
2460	Mr. H.	Neurasthenia; anemia; tuberculous infection feared.	Nos. 39, 80, 45; max. dose, mjxxv; 5 mos., intermittently.	Tangible improvement in general condition; restoration to robust health.
2461	Miss M.	Intestinal toxemia; colitis; adhesions following laparotomy.	Nos. 42, 39-A, 100, 100 and 39-A, 80; max. dose, mjxx; 7 mos. at varying intervals.	Improved general health and palliation of abdominal symptoms.
2462	Mrs. N.	Neurasthenia; typical syndrome with endocrine involvement.	No. 80; max. dose, mjviii; 7 weeks at varying intervals.	Conspicuous and cumulative response to treatment.
2463	Mr. W.	Hyperthyroidism; typical syndrome, with emphasis on the psychopathic element.	Nos. 80, 39, 100; max. dose, mjxii; 12 treatments at varying intervals.	Favorable modifications, but treatment too much interrupted for cumulative response.
2464	Miss K.	Intestinal toxemia, with neuropathic syndrome.	Nos. 39, 100; max. dose, mjvii; 4 doses only.	Treatment resumed after 6 mos. interval.
2465 ;	Mrs. K.	Pulmonary tuberculosis; advanced case; emaciated; hopeless prognosis.	Nos. 80, 39-A (to mjxviii), 39-A and 100; max. dose, mjxxxvi; 9 weeks.	A very tangible temporary improvement in general conditions, followed by the inevitable collapse.
2466	Mrs. B.	Pulmonary tuberculosis; late stage; extreme emaciation; high temperature.	Nos. 39, 39-A (to mjxviii), 39-A and 44, 39-A and 80, 75; max. dose, mjxxxvi; 30 weeks.	Pronounced improvement in nearly all symptoms for several months. Then stasis, and slow decline. Treatment continues, but prognosis more than doubtful.
2467	Miss S.	Hyperthyroidism; very typical syndrome, but without visible goitre.	Nos. 45, 39; max. dose, mjxv; several months at varying intervals by home physician.	Fairly uniform and cumulative improvement; health now better than for many years.
2468	Miss S.	Anemic obesity; hyperthyroidism; "precancerous" condition.	Nos. 39 (to mjxxv), 39-A (to mjxxv); several weeks by home physician.	Treatment has included the use of thyroid extracts and the share of the proteals in the improvement cannot be fairly adjudged.
2469	Mr. Q.	Melancholia (suicidal); susceptibility to infection; carbuncles.	Nos. 39, 39-A (to mjx), 100; 11 treatments at varying intervals.	Received benefits from early treatment, but discontinued.
2470	Mrs. M	Aortic aneurysm; hypertension with typical syndrome.	Nos. 39, 100; max. dose, mjxii; 30 weeks, at lengthening intervals.	Conspicuous progress; reduced blood pressure and modified pulsation of aneurysmal tumor, and disappearance of all subjective symptoms.
2471	Mrs. H.	Hyperthyroidism; moderate goitre; hypertension (160-90); marked gastric symptoms.	Nos. 39 (to mjxii), 100; treatment continued by home physician.	Prompt response; blood pressure reduced to 134-76 after 12 treatments; general and cumulative improvement.
2472	Miss B.	Exophthalmic goitre; recent development with typical syndrome.	Nos. 39 (to mjxv), 39 and 80, 75 (to mjxv), 80 (to mjviii); 7 mos.	Steady and progressive improvement, leading apparently to complete restoration.
2473	Mr. P.	Hyperthyroidism; a typical case, with pronounced rheumatoid symptoms, and marked leucocytosis.	Nos. 39, 39-A (to mjx), 39-A and 45; 44 (to mjxviii), 44 and 69 (to mjxvi); 23 weeks.	Slow but tangible improvement in general conditions, not as yet culminating in complete restoration.
2474	Mr. F.	Pulmonary tuberculosis; late stage, with extreme cachexia; laryngeal involvement.	No. 39-A (to mjxxv), 80 (to mjxxv), 75 (to mjxxv); 27 weeks.	Remarkable recuperation and persistent favorable progress; gain in weight, modification of cachexia; prognosis once apparently hopeless now in doubt.

A New Series of 100 Original Cases Under Proteal Treatment—(*Continued*).

(Administration, always deep subcutaneous; usually three times a week, but sometimes daily, notably in malignant cases. Initial dose, always ♏iii to ♏v, increased minim by minim or much more rapidly, according to urgency or severity of the case.)

Case No.	Name.	Principal Malady or Pathological Condition. (With Comment as to Associated Conditions or Symptoms.)	Proteal Treatment: Types of Proteals Administered; Maximum Dosage; Duration of Treatment.	Progress of Case—Chiefly with Reference to Clinical Progress. Blood Conditions Detailed in Subsequent Tables.
2475	Miss R.	Intestinal toxemia; probable mild hyperthyroidism.	No. 39, 3 doses only.	Apparent benefit, doubtless chiefly psychological.
2476	Mrs. H.	Hyperthyroidism; probable hypoadrenia and general endocrine disturbance.	Nos. 39 (to ♏xv), 39 and 80 (to ♏xv), 80 (to ♏xv), 75 (to ♏viii), 26 weeks.	Marked improvement in general condition facilitated by the use of endocrine extracts.
2477	Miss S.	Intestinal toxemia; hypoadrenia; tuberculous involvement feared.	Nos. 39 (to ♏x); treatment continued by local physician.	Marked improvement in blood and in general clinical conditions.
2478	Mr. B.	Hyperthyroidism, fairly typical case without visible goitre.	Nos. 39 (to ♏xii), 39 and 80 (to ♏xii); 10 weeks.	Satisfactory response, with disappearance of all subjective symptoms.
2479	Miss B.	Neurasthenia; familiar syndrome; dysthyroidism; hypoadrenia.	Nos. 45, 39 at variable intervals and in varying doses; treated by home physician.	Tangible but not altogether satisfactory improvement.
2480	Mr. C.	Pulmonary tuberculosis; late stage, with emaciation and cachexia.	No. 39-A (to ♏xvi), later combined with 80 (♏x); 11 weeks.	Apparent benefit for a time, justifying a less hopeless prognosis; but the patient contracted influenza and succumbed.
2481	Miss C.	Intestinal toxemia; moderate degree of asthenia.	No. 39 (to ♏vi); 2 weeks; treatment continued by local physician.	Prompt and satisfactory response to a brief course of treatment.
2482	Miss M.	Neurasthenia; rheumatoid condition; endocrine maladjustment.	No. 80 (to ♏xii); 9 weeks.	Fairly rapid progress to apparently complete restoration.
2483	Mrs. J.	Intestinal toxemia; endocrine disturbance (probable hypoadrenia), with pronounced psychopathic involvement.	Nos. 39 (to ♏xii), 39 and 80 (to ♏xii), 80 and 75 (to ♏xii); 4 mos. Treatment supplemented with endocrine extracts.	Somewhat oscillatory but cumulative improvement all along the line.

are found. Most cases of dysthyroidism are obviously neurasthenic; few if any neurasthenics are free from endocrine disturbance; many tuberculous cases show obvious thyroid anomaly; and intestinal toxemia is omnipresent. Nevertheless it will appear in subsequent tables that a certain warrant for such clinical groupings as those just suggested is found in the average blood conditions.

We are first concerned with clinical conditions; but it may be of interest by way of anticipation, to say that the hematological tables that will be presented covering the entire group of cases, will reveal blood modifications under proteal treatment having very tangible and characteristic features. Summarizing these in the fewest possible words: The hemoglobin (averaging for the 100 cases) advances under treatment from 77.03 to 87.67, or 10.64 per cent.; the red corpuscles advance from 4,601,026 to 4,915,585, an average numerical increase of 314,559, or 6.8 per cent.; and the white corpuscles decrease from 8,076 to 7,213, an average numerical decrease of 863, or 10.67 per cent. Detailed analysis of the blood conditions, of which these figures constitute a summary, will appear in a later section of this article.

A Proteal Clinic.—Such a chronological series of cases as that just presented obviously has a certain statistical value that does not attach to a group of selected cases. In discussing essential features of proteal therapy within reasonable space limits, however, it obviously becomes necessary to make selection. But I am anxious to avoid even the appearance of selecting favorable cases. It occurs to me, therefore, that a fairly satisfactory result may be attained if we take up for brief but explicit analysis the cases that actually appeared at my office for proteal treatment on a given day, in the order of their appearance. One day would serve as well as another, but June 30 was selected because it is the final day of the period which the present report covers.

The remainder of the first section of this article, then, will be in effect a proteal clinic, with comments on what I conceive to be the salient aspects of each successive case—such a running commentary as I not infrequently make before professional colleagues who personally visit my office.

It chances that 25 cases were treated with proteals on the day in question. Of these 12 are cases listed in the table above presented; the remaining 13 being newer cases. The case numbers will facilitate cross-reference.

Case I (No. 2429).—Mrs. F., age 35. This is, or was a fairly typical case of hyperthyroidism. First examined June 19, 1918. There was then a moderate but unequivocal thyroid enlargement involving both lobes. The patient was very nervous, with characteristic quick, almost spasmodic action. Highly irritable. Pulse 100. Blood pressure 120-80. History of chronic constipation, corrected in recent years. Pale looking; rather thin; had lost about six pounds in recent weeks. Very fond of coffee and of meats.

As patient was living out of town, proteal treatment was not available at the moment. Given tablets containing the nucleo-proteins of the thyroid, standardized on basis of iodine content (five grain tablets, two per cent.). Advised to discontinue coffee, and to eat meat sparingly; and to give especial attention to the condition of the bowels.

The patient returned to the city Sept. 17, somewhat improved, but with thyroid gland unmodified in size and general symptoms as before. Pulse 100. Proteal treatment began with hypodermic administration of three minims proteal No. 39. This treatment continued with a fair amount of regularity, usually three times weekly, throughout the ensuing months; the dose being increased gradually to 12 minims (at tenth administration). Larger doses were not given. The thyroid tablets were discontinued, and potassium iodide in saturated solution, one to three minims after each meal, was substituted.

Fairly uniform and cumulative improvement was noted. After two months treatment, the pulse was found always in the region of the normal, sometimes as low as 66, and never higher than 78; usually 72. The thyroid enlargement steadily decreased and is no longer noticeable. The nervousness and irritability greatly diminished; color of skin improved. Patient has gained weight and expresses herself as feeling better than she has felt for years.

The blood conditions were never bad as regards numerical count of the red corpuscles. The qualitative condition of the cells has improved. The most notable blood modification, however, pertains to the white corpuscles, which before treatment numbered 10,200, and at the last examination, after eight months proteal treatment, numbered 4,400. This patient has received only occasional proteal injections during the past two months, and seems to require no further treatment at present. The results in her case have been all that could be desired by physician or patient.

Case II (No. 2484).—Miss G., age 31. Neurasthenia, associated with anemia of somewhat chlorotic type (hemoglobin, 70; red corpuscles, 4,400,000; leucocytes, 2,700), and with disturbance of thyroid function. Asthenia; susceptibility to infections; headache and backache; skin very susceptible to local irritation—erythema following slight friction. Menses scant but extremely painful, sometimes causing complete collapse. General condition of lassitude and weakness so marked that patient, a business woman, had been unable to do effective work for several months.

Proteal treatment began Jan. 15, 1919, and has been

continued regularly three times a week. Proteal No. 39 in doses ranging up to 10 minims; then a gradual shift to Proteal No. 100 in doses ranging up to 15 minims; then a shift to Proteal No. 80 in uniform doses of about 8 minims.

Clinical improvement was marked after four or five treatments, and has been pretty steadily progressive. The patient was able to resume business actively, and on several occasions has passed through the menstrual period with very slight difficulty. All unpleasant symptoms have been favorably modified, and the patient experiences a sense of well being and a feeling of robustness and capacity for prolonged work unknown to her for at least two years before beginning proteal treatment. No other medicinal treatment has been given except that on two or three occasions thyroid tablets (nucleoproteins, two per cent. to four per cent. iodine content) have been tentatively administered for a few days before the menstrual period. Marked modification of dysmenorrhea had taken place, however, before the thyroid tablets were given, and their effect was doubtful in any event. The proteal treatment will be continued in small doses at lengthened intervals. Latest blood count shows hemoglobin, 100 per cent.; red corpuscles, 5,116,000; white corpuscles, 5,360.

Case III (No. 2459).—Mr. B., aged 23. Pulmonary tuberculosis. Patient came to me Oct. 21, 1918, with record of six years illness, during which he had been unable to work. Case had been repeatedly diagnosed as pulmonary tuberculosis, and once as bronchiectasis. several periods of sanatorium treatment. The case is atypical but unequivocal. Profuse expectoration. About 14 pounds under weight. Has much trouble with stomach. Exceedingly nervous. Heartbeat erratic, varying from 72 to 100. When beating slowly, it skipped every fourth or fifth beat.

Treatment began with Proteal No. 39, advancing rather rapidly, and substituting No. 39-A (double-strength extract of alfalfa seed protein) to facilitate larger dosage. Treatment administered three times a week, reaching a dosage of 14 minims of 39-A at the end of about two months. A gradual shift was then made to numbers 44, 45, and 80 in succession; and then to No. 75; the dosage of the latter proteals ranging up to 15 minims and then being reduced so that in recent weeks the dose has been only about 8 minims.

For about two weeks after beginning treatment, expectoration increased; after that it decreased until it was reduced to a fraction of the original quantity. Cough similarly lessened. The heart action became regular, the pulse being pretty constantly recorded as 72, and an interrupted beat noted only on rare occasions. The patient's general health and strength improved so markedly that after about six weeks' treatment he secured a job as a canvasser, and worked pretty steadily for a number of weeks, discontinuing then not so much from lack of health as because of meager financial results.

There have been sundry fluctuations in progress. At one time the patient had an acute cold with marked increase of coughing and expectoration. At another time he complained of having a dizzy spell which, however, did not recur. Again he complained of poor appetite, and was given a simple bitter tonic. But in general the clinical progress has been conspicuous, reasonably uniform, cumulative, and entirely satisfactory to patient and physician. The count of red corpuscles was supranormal (6,088,000) before treatment and has continued high, the last count showing 5,720,000. The white count at the outset showed a very marked infection (20,800). The count dropped to 9,300 after about six weeks' treatment, and subsequently came down to 6,400. The patient plans to go away for a few weeks during which time treatment will be intermitted.

Case IV (No. 2386).—Miss M., age 55. Neurasthenia, associated with high blood pressure syndrome. Suffered frequently from palpitation of the heart, superinduced by the least exertion or even by raising the arm. Heartbeat often irregular; no organic lesions.

Proteal treatment was first administered Nov. 27, 1917. Small doses of proteals numbers 45, 60, 40 and 39 at intervals of about one week. After two months' treatment, the patient reported herself as very greatly improved, no longer suffering from palpitation or disagreeable subjective symptoms of any kind. Treatment was discontinued Aug. 30, 1918, at which time the blood pressure was 160-98.

Seven months later the patient reappeared, with blood pressure 210-86, reporting a return of the old symptoms. Proteal treatment was resumed with No. 100, administered twice a week in doses ranging from four to ten minims. After two months, shift was made to Proteal No. 39. Blood pressure dropped gradually to 150-84, and at present patient experiences no unpleasant symptoms, reporting herself as feeling very well indeed. The conditions as to blood pressure are not ideal, but the pulse is soft and regular, and there is a gratifying absence of subjective symptoms. The patient expresses great satisfaction with the radical change in her condition which on two occasions, as above noted, has come about coincidentally with the administration of proteal treatment. Treatment will be continued at lengthened intervals.

Case V (No. 2415). Mr. K., age 48. Pulmonary tuberculosis of three years standing, involving both lungs. Dense fibrosis of upper lobe of right lung, with definite cavity the size of a walnut revealed by the *x*-ray. Middle lobe with diffused parenchymatous infiltration. Lower lobe with small amount of infiltration. Left lung shows definite fibrosis of tuberculosis, radiating from the root to the apex, with diffused infiltration of the lower two-thirds of the lung. Mediastinum drawn to the right by contraction of fibrosis of the right upper lobe. Patient has had about a year of sanatorium treatment in the Adirondacks. Typical cough, profuse expectoration; several slight hemorrhages. Temperature usually not far from normal. Pulse during early stage of the treatment from 80 to 100, and systolic pressure from 150 to 160.

Proteal treatment began April 24, 1918, with Proteal No. 65, shifting in succession to numbers 39, 39-A (ranging up to 15 minims), No. 80, ranging to 15 minims; shifting back to 39 and 39-A; then to 75 (maximum dose of 18 minims) and in succession 100, 41, 45, 44, 65, 80, and 75. No conspicuous local or general reaction occurred at any time. Up to date, 182 doses of various proteals have been administered.

During the fifteen months' treatment the patient has gone about his regular business and has not rested except for an occasional week-end. His general health has been uniformly good, although at times he complains of feeling rather weak, or lacking "pep." Cough and expectoration have fluctuated a good deal, but in the main have not been troublesome except early in the morning. On a few occasion the sputum has been streaked with blood. Blood pressure regressed, and after a few weeks ranged from 130-80 to 128-88. Pulse almost uniformly 72 in recent months. Temperature normal. Blood conditions satisfactory, hemoglobin having advanced from 75 to 100; the red count being maintained at normal or supranormal, and the white count (which once reached 13,200) ranging in recent months from 9,800 to 4,400. No *x*-ray has been taken recently, but auscultation reveals extension of usable vesicular area.

On the whole it may be said that the progress of this case has been eminently satisfactory. Prognosis is still doubtful, but regular proteal treatment will be continued. All that can be hoped for, of course, is slow and gradual improvement through improved nutrition and enhanced powers of resistance; and it seems reasonable to believe that the proteals are having a significant share in accomplishing this end.

Case VI (No. 2489).—Mr. J., age 27. Patient came to me Feb. 14, 1919, with diagnosis of duodenal ulcer made by competent observers at a metropolitan hospital. Characteristic syndrome. Patient reports having suffered from hyperacidity for past ten years. Had been on a milk and egg diet for past three weeks, and maintained a fair degree of comfort. Of nervous temperament but under good control.

Treatment began with Proteal No. 39, shifting from this to Proteal No. 80, dosage ranging from 5 to 15 minims. Patient's general condition seemed to be benefited from the outset, and he undoubtedly gained in strength. Greater improvement when taking the treatment regularly than in intervals of intermission. The latter, however, have been infrequent. Attempts at a more liberal diet have been made with some success but there is still a tendency to recurrence of hyperacid-

ity. Patient looks well and feels well, and is regularly and persistently at his office desk. Improvement on the whole seems satisfactory, but it is to be recalled that the patient gives a history of improvement in the summer and relapse as winter approaches. Moreover, there is a hypochrondriacal element involved. The blood conditions are not definitive, but the advance of the hemoglobin from 74 to 100 suggests tangible improvement in conditions of metabolism. The patient himself, a very intelligent man, is confident that the proteals have benefited him greatly, and the treatment will be continued.

Case VII (No. 2417).—Miss L., age 22. Pulmonary tuberculosis involving apex of left lung, of recent development. Hyperthyroidism, with well-marked goiter and slight tendency to exophthalmia. Chronic constipation. Patient first examined May 29, 1918. Temperature, 101.6°; pulse 122; blood pressure, 110. Had lost 7 pounds in recent weeks; weight then 14 pounds below maximum. Cough very troublesome.

Proteal treatment began May 31, 1918, and has continued with a single interruption during a four-week vacation period in Aug. 1918. Treatment began with Proteal No. 80, ranging up to 15 minims; shifting to No. 39 and No. 75 in sequence; reverting to 80 and then to 39-A 75, 45, and 100, with return to 80. No conspicuous reaction, general or local, at any time; unless exception be made of a momentary feeling of faintness and giddiness experienced soon after receiving the hypodermic on a recent occasion. The incident was of trifling significance, and I record it merely to emphasize its unusualness. This patient had previously received 126 administrations of proteals, and she has since then received 22 treatments, without at any time experiencing the slightest discomfort except on the occasion mentioned; nor has a similar effect, suggestive of mild anaphylaxis, been observed except in two instances among all the patients in the group above listed, to whom in the aggregate several thousand doses of proteals have been administered. The records show that on the occasion when the present patient experienced the disagreeable sensation following injection, she had a pulse of 100 prior to the injection (whereas the pulse had been before 72 and 76), suggesting that the patient was under nervous strain, making her peculiarly susceptible to the slight pain caused by accidental impingement of the needle on a nerve. The proteal administered on this occasion was 12 minims of Proteal No. 100, the same dose of this proteal having been administered on six previous visits. The two other occasions in the entire range of cases in which the administration of proteals (to patients one of whom had previously had several hundred doses without reaction) produced an anaphylactic reaction will be referred to more at length in another connection.

Progress of the present patient was highly satisfactory from the outset. Temperature came down to normal; cough diminished and there was slow but steady gain in weight, all the lost weight being regained, and two pounds added in the course of 11 months. After the summer vacation, the patient returned to work at a desk, but it appeared presently that she was not sufficiently recuperated to endure the confinement, as she developed a cough, with pronounced rales in the left upper lobe. Since then the patient has done no work, and has spent a great deal of time out of doors. She has continued to improve. Cough subsided, and presently disappeared, with slight recurrence on two or three occasions, apparently ascribable to "taking cold." Patient is looking and feeling well; there are no lung symptoms on auscultation. The pulse has at times been at 72 or thereabouts for a considerable period, but usually tends to run faster, ranging from 80 to 96. The visible goiter, meantime, has been reduced to negligible proportions, and the blood conditions no longer suggest hyperthyroidism nor do they suggest tuberculous infection. (A recent count shows: hemoglobin, 95 per cent.; red corpuscles, 4,312,000; leucocytes, 4,800). The patient is not regarded as altogether well, notwithstanding the very marked and unequivocal improvement. Treatment has been administered only twice a week of late, and the interval will be further lengthened if progress continues to be satisfactory.

Case VIII (No. 2476).—Mrs. H., age 38. This is a fairly typical example of the familiar type of cases which one labels "Neurasthenia" with full consciousness that in so doing one is begging the question as to the actual pathology involved. Patient has been out of health for 10 years. Has undoubtedly suffered from intestinal toxemia, and there are evidences of disturbance of the endocrine balance—for example, tachycardia, occasional nausea, the feeling of "quivering" in the epigastrium, susceptibility to infections, and perennial lack of energy. The provisional diagnosis of hyperthyroidism associated with hypoadrenia finds support in the results of the supplementary treatment to be referred to in a moment.

Proteal treatment began Nov. 13, 1918, and has continued with a good deal of regularity, three times a week for a time, and recently twice a week. The proteals administered were No. 39, indosage ranging up to 15 minims; No. 80, the same dose; and No. 75, with recently a few doses of No. 42. At an early stage of the treatment potassium iodide was given in doses ranging from one to three grains after each meal. At a later date, this was discontinued, and tablets of mixed glands, including thyroid and pituitary, were substituted.

The treatment was beneficial from the outset, and marked improvement was noted all along the line. There were periods of relapse, however, associated with overwork and business worriment; but in general the patient has come through a protracted period of effort exceptionally well. The blood conditions are satisfactory, with red corpuscles normal, and the white count advanced from 4,600 to 9,600, suggesting enhanced powers of resistance. A long vacation is now in order, during which the proteal treatment will be interrupted, and it may reasonably be expected that the progress will continue. In numerous cases the blood modifications due to proteal treatment have been observed to be fairly persistent where conditions are at all favorable. The present patient, however, is still taking a combination of the endocrine extracts, and it is not unlikely that she may find it desirable to do so for a long time to come. Similar cases have found it well to return for a longer or shorter period of proteal treatment now and again. Case No. 2384 in the above table, for example, is a woman having a similar disturbance of metabolism associated with intestinal toxemia and hypoadrenia, who first received the proteal treatment more than two and a half years ago, with spectacular modifications of blood conditions and general health (the case is recorded in my book, page 196), and who has received great benefit, apparently, from resort to a brief course of proteals at intervals of about six months.

Case IX (No. 2510)—Miss M. Age 23. Defective metabolism. Mild secondary anemia (hemoglobin, 86; red corpuscles, 4,158,000; white corpuscles, 8,000), associated with intestinal toxemia. "Tuberculous diathesis." Always delicate. Father died of cancer; maternal grandmother and grandfather both died of tuberculosis, as did several other near relatives in the maternal line.

Treatment began June 7, 1919, with Proteal No. 39, and has contined three times a week, dose increasing to 10 minims. At the end of the month's treatment (having received 12 doses of proteal) the patient has gained 5 pounds in weight, and expresses herself as feeling stronger and better in every way. She is now going on vacation, and will resume treatment on her return.

For purposes of comparison, reference may be made to case No. 2416 of the above table, Miss A., a girl of similar temperament, who had responded positively to the tuberculin skin test, and who had suffered from profound anemia (hemoglobin 60 per cent; red corpuscles, 2,728,000; white corpuscles, 4,400) before treatment; and who four and a half months later appeared transformed in general health and physical appearance, and showed a hemoglobin index of 80 per cent. with 5,400,000 red corpuscles and 6,000 white corpuscles. This patient had a small visible goiter, and received potassium iodide in doses of one to three grains three times daily for some weeks; but aside from this she was treated solely with proteals. No iron, arsenic, or other mineral tonic was given this patient, nor indeed to any other in the entire list.

Case X (No. 2504).—Miss S. Aged 34. Hyperthyroidism, with visible goiter, not large, involving both

lobes. Erythematous eruption simulating eczema, involving most of face. Persistently recurrent acne about the mouth and chin. Skin in general sensitive, coming up in welts on pressure. Has suffered for years from "intestinal toxemia," for which she reported having received "serum" treatment. Ultimately had appendix and gall-bladder removed.

Proteal treatment began May 9, 1919, with Proteal No. 39, and was continued pretty regularly three times a week, the dose advancing to 15 minims. There has been marked improvement in the general condition, and a very notable modification of the facial eruption. A few spots of acne remain, but the disfiguring eczema has gone. It should be noted that an antiseptic ointment was prescribed for application to the face. The eruption had previously resisted various other treatments, however, and it may plausibly be assumed that the modification of blood conditions due to the proteals aided in ameliorating the skin conditions. There has been a notable improvement in the conditions of digestion and in the patient's sense of well being. The pulse, which is recorded as 84 to 94 during the early visits, dropped presently to the normal range, and is now recorded regularly as from 72 to 76. Progress has been in every way satisfactory, and it probably will not be necessary to continue treatment for a very long period.

Case XI (No. 2464).—Miss K. Age 45. Intestinal toxemia; psychasthenia. Typical case of familiar type. First came for treatment No. 13, 1918, but interrupted treatment after receiving three doses of Proteal No. 39 (owing to circumstances having nothing to do with the treatment), and did not resume until June 30, 1919. Expects now to take treatment regularly, and is taking Proteal No. 100.

(Note. The day of actual writing of this report, the patient has received nine doses of Proteal No. 100, the last four doses with an admixture of No. 39. She shows marked improvement, and expresses herself as feeling greatly benefited.)

Case XIII (No. 2459).—Mrs. K. Age 32. Hyperthyroidism. Conspicuous goiter of two years' standing, involving both lobes; the right lobe more markedly. Moderate toxicity, with typical syndrome.

Proteal treatment began April 4, 1919, and continued with Proteal No. 39 in doses ranging up to 15 minims. No other treatment except potassium iodide, saturated solution, in doses of one to three drops after each meal.

After seven proteal injections the patient reported that she could take long walks without fatigue, which hitherto had been impossible; and that she felt better than for years. The goiter had been conspicuously reduced in size as shown by a photograph taken before treatment. Improvement has continued, the goiter continuing to regress, and the general condition of the patient being in every way satisfactory. The pulse, which at first was about 100, now ranges from 75 to 80. It will of course be necessary to continue treatment for a considerable period, but the very marked progress already noted justifies a favorable prognosis. The records of other cases serve to fortify the inference that the conspicuous modifications noted are associated with the improved conditions of metabolism due to the administration of the proteals. Of course the probably direct action of the iodide in supplying a presumptive defect of the thyroid secretion is not to be overlooked. It is not to be credited, however, that iodide of potassium by itself could accomplish the really spectacular modifications observed in some goiter cases under proteal treatment.

Case XIII (No. 2423).—Mrs. M. Age 58. Nocturnal epilepsy, of 15 years' standing. Patient is pale and very anemic (hemoglobin 55-60; red corpuscles, 3,824,000; white corpuscles, 7,200). The epileptic seizures formerly came rather frequently, always at night, and left the patient extremely debilitated.

Proteal treatment was instituted tentatively, in the hope of improving blood conditions and thereby bettering metabolism in general, with the thought that an indirect modification of the seizures might result from improved bodily conditions. The expectation appears to have been justified. Proteal treatment was begun May 20, 1918, the proteals administered being No. 42, in doses ranging up to 12 minims, followed by No. 80, and then by numbers 39 and 75 in sequence; ultimately reverting to No. 39. Large doses have not been given—never more than 10 or 12 minims.

Patient showed marked improvement in general condition. Moreover, two months and ten days elapsed before she had a seizure; and after that another interval of nearly four months. One month later she had another attack, and then no return until after a lapse of three months. These intervals are much longer than the usual intervals between attacks before the proteal treatment was begun. The patient has not taken the treatment with entire regularity, but in the aggregate has received seventy-seven treatments in the period of a little over thirteen months. The patient and her friends feel that she has greatly benefited from the treatment, and it will be continued. Obviously one can draw no inference from a single case as to the probable benefits to be derived from proteal treatment by epileptics in general; and I have treated only one other case (Case No. 2456 of the table), with results not at all definitive.

Case XIV (No. 2485).—Mr. B. Age 63. Patient came to me January 17, 1919, with diagnosis of carcinoma of the bladder made at a metropolitan hospital. History of pain associated with tumefaction in perineal region; difficult and painful micturition; paroxysms of intense pain in lower abdomen; loss of weight and strength. Very thin and markedly cachectic. Blood conditions support the diagnosis of carcinoma, moderately advanced, showing hemoglobin 80 per cent.; red corpuscles, 4,902,000; white corpuscles, 11,600. Urine with 0.10 per cent. albumin.

Proteal treatment was begun January 27, 1919, and was advanced pretty rapidly in dosage up to a maximum of 20 minims of 39-A (double-strength extract of alfalfa seed protein). This dosage was continued for a time and then a shift made to No. 80. After receiving on April 11, a dose of 10 minims of No. 39-A and 10 minims of No. 80, the patient felt ill and for a time lay down on a settee in the hallway before leaving the building; and half an hour later experienced pronounced itching on the legs and flanks. A mild anaphylactic reaction, apparently; this being one of the exceptional cases above referred to. There has been no recurrence, although the patient has received many additional treatments.

The patient has markedly improved in general condition, and there has been conspicuous amelioration of the pain, which disappeared altogether in the abdominal region, and recurred only occasionally in the region of the perineum. Micturition is at times painful. Five months after treatment began, urine showed albumin reduced to 0.05 per cent. The patient is able to work pretty actively in his garden and to make the rather tedious journeys to my office for treatment. Treatment will be continued, with prognosis in abeyance.

Case XV (No. 2584).—Mr. T. Age 49. Chronic pharyngolaryngitis, with almost complete aphonia. Condition supposed to be specific or tuberculous, but all tests negative. Blood examination August 12, 1918, and October 9, 1918, showed rather marked leucopenia, with supranormal red-cell count. It was thought that the proteal treatment might modify this and build up the powers of resistance.

Proteal treatment began June 2, 1919, Proteal No. 39 being given twice a week in doses ranging up to 12 minims.

The patient had greatly improved in general condition and regained control of his voice to a considerable extent before the proteal treatment was begun. Improvement continued and the patient appears to have regained something like normal control of his vocal apparatus, except that he clears his throat constantly. As the patient was improving before beginning proteal treatment it would be futile to ask what share this phase of treatment had in contributing to the general result. It may be noted, however, that the qualitative conditions of the red corpuscles are now much less abnormal, and it may reasonably be inferred that proteals have had a share in this normalization.

Case XVI (No. 2404).—Miss K. Age 31. Chronic arthritis, probably associated with hyperthyroidism.

Proteal treatment began March 14, 1918, and has

been continued with various intervals. Proteals No. 63, 39, 45, and 80 have been used, in dosage varying from 5 to 15 minims.

The rheumatoid pains, associated with swollen joints of the fingers, ankles, etc., appeared to yield to treatment rather promptly. At present patient is free from rheumatoid symptoms and is enjoying excellent health, but the painful swelling involving the ankles recurred a few weeks ago, and proteal treatment is to be continued for a time as a precautionary measure.

Case XVII (No. 2385).—Mr. E. Pulmonary tuberculosis of 25 years' duration. A typical example of the not unfamiliar type of tuberculous case in which the organism and the invading bacilli are apparently at a deadlock. There is partial fibrosis of portions of the lungs, and there are areas of active infection. Cough persistent, with abundant expectoration of germ-laden sputum. The patient is thin, frail, seemingly with a very slender hold on life, and yet he lives on from year to year and manifests a really extraordinary amount of vitality. In the present instance, the patient was cachectic, his pallor being such that he would be a marked man in any company even of invalids. For years past he has spent the winters in Florida and the summers chiefly in boating on Great South Bay. He regards perpetual vigilance as the price of living.

Proteal treatment was begun Nov. 24, 1917. It has been continued with a considerable degree of regularity since that time, except for an interval of three or four recent months. The patient has administered the hypodermics himself, and the proteals used have included numbers 45, 39, 80, and 75, in doses ranging from five to twenty minims. No other treatment has been employed throughout the period.

Changes in the patient's condition have been very notable indeed. After a few months of treatment, he entirely lost the cachectic appearance, developing a fairly good color. Cough continued, but the quality of the sputum was conspicuously changed, becoming lighter in color and assuming what was described as a sweetish taste. Quantity diminished but has not been reduced beyond a certain minimum, and is still sufficiently troublesome. Patient remained in the North throughout the winter of 1917-1918, and suffered no disturbing consequences. General health was and continues to be better than for many years past. He spent the past winter in the South, and for a time discontinued proteal treatment, which, however, he is now to resume. He feels that the benefits derived from the use of the proteals have been definite and material; and it is hardly to be denied that his experience justifies him in feeling that he is a good judge of his own condition. As the improvement in general health and modification of the sputum and blood changes came about without change of environment or habits, coincidently with the inauguration of proteal treatment, it would appear that the evidence for the value of the vegetable proteins in this case is fairly conclusive.

Attention may be called to the even more notable case of tuberculosis, Mrs. K., No. 2389 of the above table. A fairly full account of the earlier history of the case was given in my book, "The Proteomorphic Theory and the New Medicine," page 191, and it is gratifying to be able to record that in the ensuing year the patient's progress has been all that could be desired. In recent months she has come only now and again for examination and to receive a small dose of proteal as a precautionary measure. Recent sputum examination, negative as to tubercle bacilli.

Case XVIII (No. 2488).—Mrs. M. Neurasthenia associated with mild anemia. Usual syndrome—headache, backache, lack of energy, inability to make mental application, susceptibility to "colds" and other infections.

Proteal treatment began February 3, 1919. Proteal No. 80 was given in doses ranging from five to fifteen minims for a period of three months, and then No. 100 in doses of eight and ten minims.

The patient appeared to respond to the proteal treatment from the outset, and after two weeks' treatment felt so much improved in general condition and mental energy that she was able to begin creative work (writing) which had long been interrupted. Continued to improve and has attained approximate normality, but still comes at lengthening intervals for proteal treatment, to guard against relapse.

Case XIX (No. 2518).—Mr. H. Age 67. Carcinoma of the mouth and throat. Postoperative recurrence in the floor of the mouth on the right side under and involving the tongue. The original growth appeared in November, 1918, and developed rather slowly. An operation in March, 1919, removed the growth and the glands of the neck. The lesion did not heal kindly, and a larger growth rapidly developed under the tongue at the seat of incision. The patient came to me June 16, 1919, at which time the lump was hard, slightly tender, and at times very painful; the size of a large walnut.

Treatment began with Proteal No. 39, advancing the dose rapidly; administered daily; shifting to 39-A for convenience in giving larger doses; and increasing this to twelve minims; then combining with Proteal No. 100 and advancing dose until the daily hypodermic comprised ten minims of No. 39-A and fifteen minims of No. 100.

After the second injection, the neoplasm and surrounding regions of the throat were very tender for several hours. Until after the seventh injection, there was occasionally much pain in the throat and under the tongue. After this, pain was no longer noticeable, although the patient complained of soreness on swallowing. The soreness of the throat disappeared, and the pain on swallowing was confined to the immediate region of the neoplasm.

(Continuing the history of the case to the date of present writing. On July 8, after twenty treatments, it was observed that the tumor had begun to slough on the right side. Sloughing continued and extended across the tumor to the left side, involving the entire mass, to the depth of about a quarter of an inch. The sloughed masses, necrotic in character but only slightly malodorous, were readily removed with the dressing forceps. No application had been made to the mass until the sloughing began, and then only tincture of iodine in small quantity on an applicator, and a modified Dakin-Carrel solution as a mouth wash. Coincidentally with the changes in the neoplasm proper, the hardness and thickness of the tongue were conspicuously lessened. All soreness of the throat has disappeared excepting one localized spot, near the angle of the jaw. At times a feeling of gnawing or clutching at the throat is experienced. The patient's general condition has much improved, and at date of writing (July 24) he reports having gained two pounds in weight in the past week. As a matter of course, prognosis is held entirely in abeyance. The progress already noted is typical of early results in similar cases with the use of the proteals. But past experience shows that the vital problem now is how to increase the dosage or substitute new proteins in such a way as to keep up the corpuscular enzymic response through which the neoplastic cells are being broken down. We have crossed the first trench, but the fight is not yet won).

Case XX (No. 2497).—Mr. A. Pulmonary tuberculosis of about three years standing, involving upper lobe. Several severe hemorrhages in the past. Has had about a year of sanatorium treatment, with marked benefit. There is evidence now of arrested development, but patient lacks vigor, is unable to work, and feels the need of treatment to improve nutrition, and hold the infection permanently in check.

Proteal treatment began April 7, 1919, with Proteal No. 39, advancing to a dosage of fifteen minims; shifting after about two months to Proteal No. 80 in doses of from eight to twelve minims; and then to Proteal No. 100.

In a case of this character, in which marked improvement was under way before the proteals were administered, it is difficult to form an opinion as to the specific effect of the treatment. Patient, however, reported a change in the character of his sputum, soon after the treatment began. He feels an enhanced

sense of vigor and strength, and is himself entirely satisfied that the proteals have had a large share in contributing to his present satisfactory condition.

Case XXI (No. 2515).—Miss D. Carcinoma of the breast. Both breasts involved, and glandular system in the region of the left breast and arm. The tumors of the breasts are smaller than eggs, but the glandular involvement is such that an operation was deemed inadvisable at the Mayo Clinic. The lump in the right breast developed almost nine years ago, following an injury. The neoplasm in the left breast is of two years' standing. The patient suffers excruciating pain of characteristic lancinating character at times. Incidentally it is of interest to note that she is reported as having had pulmonary tuberculosis many years ago, with complete recovery.

Proteal treatment began June 13, 1919, with Proteal No. 39, shifting presently to No. 39-A. The patient experienced a mild local reaction, and after the fourth injection (10 minims) noted a "pulling" at the breast that had not hitherto been experienced. Following the succeeding dose, the breast was very painful for a time. After eight injections, the patient is confident that the lump in the left breast is distinctly smaller; and that in the right breast, which was never much larger than a walnut, is decidedly softer.

Note At the time of the present writing, July 24, the patient is receiving Proteal No. 39-A in combination with Proteal No. 100, and is progressing satisfactorily, although of course treatment has been instituted for far too short a period to give any warrant for definite prognostications. A purplish spot in the region of the neoplasm on the left breast suggests the possibility of a breaking down of tissues, which is to be desired. A similar case under proteal treatment, in which such disruptions occurred with discharge of part of the substance of the broken-down neoplasm, thus limiting the amount of tissue to be absorbed, resulted in apparently complete recovery. It is hardly to be expected that a case so far advanced as the present one will be carried to so satisfactory a conclusion; but experience justifies the expectation of marked amelioration under proteal treament, greater, in my opinion, than could be expected from any other method of treatment at present available.

For purposes of comparison, attention may be called to Case No. 2420 of the above table. The patient, suffering from postoperative recurrent carcinoma of the breast, after undergoing radium treatment, was confined to bed, and supposedly approaching a moribund condition in April, 1918. Proteal treatment was instituted as a forlorn hope. She revived, gained strength, was able to be about, conducting herself and enjoying herself like a normal person. She came to New York to be under my personal supervision, and gained eleven pounds in weight in about six weeks. For more than a year—receiving large doses of proteals daily—she maintained the outward appearance of health, and had a cheerful and happy existence. It proved impossible to heal the enormous lesion involving the regions of both breasts. There was, however, no malodor after the beginning of proteal treatment, and the lesion had the appearance of a healthy granulating abrasion, except that there was the characteristic tendency to formation of nodules about the borders. Ultimately metastases occurred into the lungs and possibly the spinal cord. The patient declined rapidly and died in her sleep June 25, 1919. In the opinion of her physician, there was no question that the patient's life was prolonged at least a year, solely by proteal medication; and it should be emphasized that this period of extended life was not passed in misery but in comfort and without use of opiates until a few days before the end. Acquaintances and even close friends of the patient were with her frequently without suspecting that she suffered from a serious malady.

Case XXII (No. 2509).—Mrs. R. "Lenticular paralysis" associated with marked anemia. Diagnosis made at the Neurological Institute before the patient came to me. The patient had been under treatment with proteals from my laboratory for several weeks before she came to me for further treatment June 4, 1919. Proteal No. 39 was continued and presently supplemented with No. 100, which will be continued. Considering the character of the malady, it is obvious that any progonostications beyond the suggestion that the blood conditions and general health may be benefited by the proteals, would be unwarranted.

Case XXIII (No. 2511).—Mr. R. "Aortic aneurysm" Diagnosis made by competent roentgenologists before the patient came to me. Diagnosis questioned by a prominent heart specialist after a subsequent *x*-ray examination; but no satisfactory diagnosis substituted. The patient has suffered from extreme functional disturbance of the heart for several years, associated with frequent periods of great precordial distress for which tetranitrates and nitroglycerin have been taken persistently for the past four years. The condition is probably associated with an endocrine maladjustment; but it is far easier to make this vague suggestion than to localize the disturbance. When the patient first came to me May 29, 1919, his blood pressure was 150-100; pulse 100; blood count supranormal—hemoglobin 105 per cent., red corpuscles, 5,568,000; white corpuscles, 8,240. These conditions suggest overaction of the thyroid.

At this time the patient was already taking proteals from my laboratory with apparent benefit. He came to me for direct treatment June 4, 1919, and Proteal No. 39 was continued for a few treatments, and then No. 100 substituted, which will be continued.

The patient has been able to reduce markedly the amount of nitroglycerin taken, and has experienced less precordial distress and dyspena. The pulse is extremely variable, ranging from 75 to 100. The erythrocytosis (a frequent concomitant of hyperthyroidism) suggests defective enzymic activities of the corpuscles, which may be corrected by proteal treatment. It is not unlikely that blood pressure will be lowered coincidently with more extended use of the proteals. The general conditions of metabolism may be favorably modified, improving nutrition. If my surmise is correct that there is a disturbance of the suprarenal-pituitary-thyroid triumvirate, the proteals may have a share in tending to restore the balance through the great endocrine system of the blood-forming mechanism and corpuscles. All this is very vague, and the case is reported here merely for the sake of completeness.

It will be of interest, however, in view of the provisional diagnosis above noted, to call attention to case No. 2470 of the clinical table, a case of obvious aneurysm of the arch of the aorta protruding between the ribs and forming a pulsating tumor the size of a small egg bulging over the left side of the sternum.

The patient came to me in November, 1918, with pulse 120, blood pressure 170-80. Complained of extreme dyspnea on the slightest exertion, and more or less constant giddiness and sense of fullness in the head. Previous treatment, at the hands of a local physician, had included Liq. Arsen, et Hg. Iod., in four minim doses and potassium iodide in eight grain doses after each meal.

The proteal treatment was begun Nov. 22, 1918. The patient was told to continue for a time the mixture just cited, in order that any changes observed might not be ascribable to omission of these remedies. Proteal No. 39 was given in doses ranging from the initial three minims up to twelve minims. Almost from the outset the patient began to experience amelioration of the unpleasant symptoms, and after about the tenth dose she reported herself able to go upstairs, walk rapidly, and perform various household duties without any feeling of discomfort.

In the meantime the blood pressure had been reduced to 130-66 and the pulse was 76. The iodide prescription (which, it should be noted, had been taken without apparent effect for several weeks before the patient came to me) was discontinued, and thereafter no medicine was given by the mouth except, on one occasion, pancreatic tablets to remedy a temporary indigestion. Proteal treatment was given three times weekly for about six weeks, and after that twice weekly for a time, and then at weekly intervals, Proteal No. 100 being substituted in recent weeks.

The gratifying alterations in the patient's feelings has continued without interruption. She has a sense of well being, and no discomfort of any kind. The tumor itself is reduced somewhat in size, and the pulsations are no longer so pronounced as to be subjectively observed. When last taken, the blood pressure was 120-60,—not quite a proper balance between the systolic and the diastolic pressures, but apparently connoting conditions of satisfactory distribution of the blood supply. The patient left for her summer vacation on June 25, taking with her a supply of proteals to be administered, if needed, by her local physician. It is rather to be expected, however, that the satisfactory conditions that have obtained for six months will continue for a time at any rate without further proteal treament. The satisfactory blood conditions (hemoglobin, 80 per cent.; red corpucles. 4,232,000; white corpuscles, 7,000—contrasted with the original 15,200) justify this expectation, as it has been repeatedly observed that when the blood conditions have been normalized, by a course of proteal treatment, the conditions of improved metabolism tend to persist.

Case XXIV (No. 2506).—Mr. E. Intestinal toxemia with persistent glycosuria. Diagnosis of chronic diabetes made by various physicians during several years. Urine negative as to sugar on day of my first examination, May 26, 1919; but positive, ranging from 1 per cent. to 1.6 per cent. on subsequent examinations. Specific gravity, 1024 to 1027; urea from 1.4 per cent. to 2.3 per cent. The blood count showed: hemoglobin, 107 per cent.; red corpuscles, 5,880,000; white corpuscles, 8,080. Characteristic clinical syndrome of diabetes. Has been on a diet for years. For "eighteen years" has felt a painful lump now and again in the stomach, and suffered from "heartburn", both symptoms tending to disappear after eating. Persistent constipation.

Proteal treatment began May 28, with Proteal No. 100; continued in doses ranging from four to ten minims. After ten treatments, the patient reports himself as feeling very greatly improved; he is handling his food better, and is working daily with much less sense of exhaustion. He notes that the urine has changed in quality, being no longer red and odoriferous. Proteal treatment will be continued, and a more liberal diet attempted.

It seems a reasonable assumption that the proteals are improving the conditions of metabolism, as they appear to have done effectively in the only other case of diabetes in the list of patients now under examination, Case No. 2430 of the table.

Case XXV (No. 2472).—Miss B. Age 28. Exophthalmic goiter. Conspicuous enlargement of right lobe of thyroid gland, which was first noticed by the patient only about five weeks before coming to me, but which doubtless had been developing for a much longer period. Marked exophthalmia. Backache, headache, lassitude, and marked but not excessive nervousness.

Proteal treatment began Dec. 6, 1918, Proteal No. 39 being given in doses ranging from four to fifteen minims for a period of about two months. Then gradual substitution of Proteal No. 80 for a short time, and then No. 75, which was continued for about two months, before reverting to No. 80; the last named being given in doses of from five to eight minims three times a week. No other medication, except the saturated solution of potassium iodide, in doses of from one to three minims after each meal.

Improvement under proteal treatment was almost immediate and it continued and was cumulative. After six doses the patient observed that she found vegetable proteins a "great tonic." There was a new sense of well being, and she found herself able to perform her daily tasks with increasing energy and satisfaction. The goitre was very markedly reduced in size after about one month's treatment, and it continued to regress until it was no longer observable. An attack of tonsillitis interfered only temporarily with the general progress, and week after week the patient reported herself as "feeling fine." There was, however, an interesting complication, in that a rash appeared on the body in localized spots after treatment had been under way for a few months, which developed into a fairly typical psoriatic eruption. The spots were never larger than a dime, diffluent and confined to the chest, back, and exceptionally to the arms.

When the eruption first appeared I thought it might conceivably be an anaphylactic phenomenon due to some constituent of Proteal No. 80. I therefore substituted No. 75, with its entirely new group of proteins. The eruption continued, after a momentary period of apparent regression. Chrysarobin ointment was applied to a few of the spots with effective results; but the patient objected to the discoloration and the ointment was not used extensively. Nevertheless, all the spots began to fade after having persisted for about six weeks. I now used Proteal No. 80 again, to test the theory that the eruption might have been superinduced by one of the proteins in that combination; but the eruption continued to fade and has practically cleared up altogether without further local treatment.

After seven months' use of the proteals the patient's condition is so satisfactory in every way, that there seems no present need of further treatment. The potassium iodide had been discontinued some weeks earlier, and only small doses of proteal given during the later stages of the treatment. All symptoms of hyperthyroidism, including the enlargement of the thyroid itself, have disappeared. The patient's eyes are, indeed, slightly protuberant, but not more so, she believes, than they were in the old pre-goiter days. In a word, recovery appears to be complete. Whether the conditions of intestinal toxemia and disturbed metabolism by which the goiter was superinduced, or with which it was associated, have been permanently corrected, remains to be seen. The patient now goes on vacation, with instructions to live hygienically, paying especial attention to the condition of the bowels; and otherwise to give no thought to her condition.

The development of an eruption persisting more than a few hours in a patient under proteal treatment, as recorded in this case, is a unique experience. I have suggested the possibility of the proteins causing the eruption. It seems more than probable, however, in view of the history of other cases, that the eruption was due to the same conditions of disturbed metabolism that underlay the goitre, and that the use of the proteals facilitated the regression of the eruption. The spectacular results of the treatment of several cases of psoriasis with the proteals justify this conclusion.

Case No. 2413 of the above table, for example. This patient, Mr. A., suffered from psoriasis of long standing that had resisted treatment at the hands of many specialists. Arms, large areas of the body, and hands involved. Desquamation so free that a carpet sweeper was kept at the bedside. Response to proteal treatment (no local application) was prompt, the eruption being modified appreciably after six doses of No. 65. Progress was uninterrupted, the body areas clearing first, and the hands, arms, and wrists in sequence. At last report, almost a year later, patient was in fine general condition, and his skin perfectly clear.

This completes the series of 25 patients treated by me with proteals on the day in question. Discussion and analysis of the theoretical explanation of the application of this therapeutic agent in so wide a range of maladies, together with a summary of blood conditions, is reserved for the second article. Here in concluding the clinical presentation of a group of my own recent cases, I wish only to make very brief comment by way of answering two questions that have doubtless come into the minds of many readers of the foregoing pages, namely:

1. In presenting this series of cases, in which results almost uniformly good, and sometimes spectacular, appear to have been attained from the use of the proteals, has the author given proper consideration to the benefits that may have resulted from the application of other remedies coincidently with the proteals? And, contrariwise:

2. Has full consideration been given to the pos-

sible psychical factors of the hypodermic treatment?

As to the first question, let me say that I assuredly do not undervalue the aid of such simple measures as diet, hygiene, exercise, and the use of laxatives as auxiliaries in the treatment of a large proportion of cases of disturbed metabolism. I have been for more than 35 years a physician, and I personally treated a good many thousand cases of the most varied character in days that antedated the introduction of serums and vaccines, not to mention nonspecific proteins.

If a man who has had this experience is ever able to forget the importance of such gigantic "small things" as, for example, laxatives, in dealing with maladies of almost every type, he has small aptitude for the practice of medicine.

Let it be clearly understood, then, that I have given attention to the digestive apparatus, and in particular to the elemental matter of regulating the bowels, in every case under consideration in the present paper, as in every other one in all the thousands of cases I have treated in the past. I entertain no doubts that this auxiliary treatment has contributed to the gratifying results noted. But I feel equally certain that such auxiliary treatment by itself—including full attention to diet, hygiene, exercise, and the action of the emunctories—would not have sufficed to produce the striking modifications in the corpuscular status, blood pressure, enzymic activities, and varied specific pathological conditions of which these clinical records give evidence.

If proof were needed of this proposition, it might be found in the citation of the fact that most of these patients were chronic cases that had gone from physician to physician and had been subjected to one line of treatment after another. The auxiliary treatment had been found inadequate. The modifications that were brought about when the proteals were given, in a majority of cases, were so definite and tangible as scarcely to admit of challenge. I have said in my book and I unreservedly repeat, that certain results in the administering of nonspecific proteins are so tangible and so fully demonstrated that they are scarcely more to be questioned than the elementary facts about the action of such drugs as quinine, morphine, and digitalis. The justice of this predication will be still more evident, I trust, when further presentation of facts and theories is made in the next article.

Now an even briefer word as to the secondary question—as to whether I have given full consideration to the psychical element; whether, in short, the changes observed coincidently with the administration of the proteals may not have been due, at least in some instances, to the effect on the patient's mind rather than to the effect on his or her corpuscles.

As to this, it will perhaps suffice to note that for more than ten years I specialized as a psychiatrist, the practical experience of that period bringing me in close contact with perhaps 10,000 mental cases; therefore I am not likely to underrate the value of the psychical element in therapeutics. It would be absurd to deny that confidence in a physician is an important element in any patient's reception of any treatment. It need not be doubted that a certain number of patients of neurasthenic type would appear to receive great benefits from a hypodermic of water. But let me repeat that most of the cases under consideration had tested the treatments of many physicians in succession before coming to me; and, moreover, presented definite pathological entities—goiter, cancer, tuberculosis, anemia—far from imaginary.

Then it must be recalled that from the outset I have tested the results of proteal treatment with the microscope. I have by no means depended upon clinical findings alone. Faith is said to move mountains (though I do not understand there is a photographic record to support the allegation) but I am not aware that faith unaided will quickly modify the hemoglobin index, the number of red corpuscles, or the differential count of the leucocytes. It would be faith of a new order that could cause tubercle bacilli to disappear from the sputum, cancer cells to autolyze "spontaneously," ulcers to heal without local treatment, rheumatoid joints to lose their stiffness, asthmatic bronchi to relax, and goiters to regress. If proteals can inspire that kind of faith, then assuredly they are entitled to a high place in the armamentarium of the physician.

It is hardly necessary to add that I do not suggest for the proteals any such esotericism of action. I suggest a very definite and tangible physiological response to a therapeutic agent of the most practical character. Details as to the nature of this response and fuller analysis of the physiological principles involved will appear in another article.

THE NECESSITY OF ACCURACY IN THE DIAGNOSIS OF TUBERCULOSIS.

By M. JAMES FINE, M.D.,

NEWARK, N. J.

CHIEF OF THE DIVISION OF TUBERCULOSIS OF THE NEWARK BOARD OF HEALTH.

In speaking of accuracy in diagnosis I have in mind primarily the early diagnosis of the suspected case; cases that are moderately advanced do not require special technique and can be easily discovered. It is in early cases where the greatest good can be accomplished. The symptoms that are present in incipient tuberculosis are sometimes so insignificant as to be almost negligible, and it is hardly ever the case that the patient himself heeds their warning and presents himself to his physician for examination.

This state of affairs was strikingly brought to our attention in the work of the Selective Service Examining Boards. Many cases that would not have come under observation of the physician were discovered through the selective draft and were put under proper care. As a member of an advisory board I can speak from experience. Many selectives were shown to have incipient tuberculosis and were well-nigh dumfounded when apprised of their condition; ofttimes they would scoff at the findings of the examining physician, asserting emphatically that they were always in the best of health or that the symptoms were so mild as to cause them only slight inconvenience, and which they thought were of a transitory nature.

The truth of the board's diagnostic findings was, however, very unpleasantly demonstrated to many of them in the progressing gravity of their tuberculosis, and a great number of these selectives are now under treatment in various city and county sanatoria.

It is the neglect of the apparently slight and unimportant signs and symptoms and the carelessness on the part of some physicians through making a merely cursory examination, or the treatment of the patient symptomatically without any examination at all, that are responsible for untold injustice being done to a vast multitude of tuberculous individuals.

It is, moreover, very surprising that the errors in making diagnosis in tuberculosis are generally errors of omission rather than of commission; for while it cannot possibly do any harm to advise a person suspected of tuberculosis to take a rest and submit to the proper care and management necessary in tuberculous disease, it is an absolutely criminal procedure to pronounce a man free from tuberculosis when such is not really the case. This point is well illustrated by a statement of Dr. L. G. Ehrenreich, formerly of the Montefiore Home, when he says: "I can safely say without hesitation that the physician's neglect in not properly examining and diagnosing pulmonary tuberculosis is responsible for more than 20 per cent. of our advanced cases." He further states that at least 50 per cent. of his patients were sick at least six months before seeking medical advice.

Considering the almost universality of tuberculosis as proven by the observations of Calmette and von Pirquet, who find that 90 per cent. of all children between the ages of 1 and 15 years are infected with some form of tuberculosis, and that in from 91 to 97 per cent. of young people above that age the same condition exists, we should suspect every person presenting himself for examination manifesting any symptom or sign, be it ever so slight, of suffering from tuberculosis. This conclusion or suspicion should be held until, by the employment of all diagnostic means known to science and taking all other factors into consideration, the diagnosis of tuberculosis can be excluded, but not until then.

A scheme of arriving at an accurate diagnosis which has been followed out by the author and others consists in the application of all the scientific means in conjunction with the family and personal history, subjective and objective signs and symptoms manifested by the individual case.

Under the head of subjective symptoms I consider valuable: Hemoptysis; slightly accelerated pulse and slight elevation of temperature in the afternoon; fatigue on slight exertion; loss of weight; short cough with or without sputum.

To obtain the objective physical signs we must resort to the following method: The patient is stripped to the waist line and seated at ease on a stool with muscles relaxed and face towards the window so that the movements of the chest can be properly observed.

The retractions or grooves above and below the clavicles, deformity of the chest, atrophy of muscles and limitation of movement of the affected part, can be noted in an exact manner through the use of the thoracimeter. If accuracy is desired and measurement is to be recorded, it can be accomplished by the use of this instrument (**Jour. Amer. Med. Assn.*, 1916, lxvi, 186). The use of the thoracimeter is based upon the recognition that a diminution in the expansive power of the lung, no matter what the particular explanation for it may be, is now unanimously regarded as one of the early signs of apical disease. The muscular contractions and spasms pointed out by Pottenger can also be accurately appraised by the use of this instrument.

Palpation is an aid in estimating the resistance, fremitus, and movements of the chest. By putting the palm of each hand on the corresponding side of the chest one can feel the resistance and movement of the thorax. Placing the hand over the apices with the tips of the fingers just below the clavicles and using equal pressure and asking the patient to breathe a little deeper than normally, one will notice that the affected side will not give as much resistance as the other side. One can also by this means detect the muscular spasm so well described by Pottenger.

Tactile fremitus is usually increased on the affected side, but generally occurs later in the disease.

Percussion has established itself as being useful in ascertaining the existence of incipient tuberculosis. It is an act to elicit sounds of vibration by striking. I prefer the use of the medium and light stroke, percussing from below upwards, comparing each side. The apical isthmus can be nicely mapped out on percussion where one finds a contraction on the affected side. Sometimes a slight alteration in the pitch of the percussion note is the only physical sign of a tuberculous process. Variation of pitch and duration of sound are very important to determine the resonance at the midaxillary and scapular lines. To obtain this the patient is instructed to hold his breath at the end of inspiration and again after full expiration; the width of the excursion is measured and recorded. This measures the movements of the lungs in the pleural sinus and it is often found absent or decreased on the affected side.

Auscultation is the most practical method applicable in detecting incipient tuberculosis. Bendlier calls attention to the hoarse vesicular sound in early lesions at the apex. I find the whispered voice method described by Beifeld is very helpful. The patient is instructed to whisper one, two, three, several times in a single breath, followed by a deep inspiration. This will bring out the apical râles. Prolonged expiration is very insignificant in early diagnosis, but is not always due to tuberculosis. Fine persistant râles limited to one portion of the lung, if they do not disappear on coughing, are generally the most trustworthy sign in early tuberculosis. They are best elicited by telling the patient to expel forcibly all the air from his lungs followed by a short cough, after which inspiration must follow. Râles that occur symmetrically at both bases without any dullness or change in breath sounds are not tuberculous. The same is the case with marginal râles. To eliminate adventitious sounds and râles, caused by heavy breathing, such as those in the costosternal articulation or sterno-

*Read before the Academy of Medicine of Northern New Jersey, March 11, 1919.

clavicular crackles. The author uses the following method: Instruct the patient to cross his arms to the opposite shoulder and hold them firm against his chest. The patient is then instructed to breathe easy, which will also give one a chance to hear the constant râles in a robust muscular individual. We must always keep in mind pathological conditions in the nose will sometimes transmit peculiar sounds to the chest; in these cases mouth breathing is best.

d'Espine's Sign.—In normal children auscultation over the spinous processes reveals tubular breathing, as low as the bifurcation of the trachea. In case of enlarged glands of mediastinum, in children especially, tubular breathing is heard lower down.

It requires all the skill that an examiner has at any time to be able to say that tuberculosis is not present. In children the disease is usually limited to glands which can only be discovered by the *x*-ray. Tuberculosis of the hilus, parenchymatous infiltration, and the fan-like expansion of the peribronchial type can be detected only by the *x*-ray.

In questionable cases repeated examination should be made and all scientific methods applied, such as complement fixation, radioscopy, skin test, etc.

It is impossible to say that any one method or sign is best used in detecting incipient tuberculosis, for much depends upon the examiner's experience or perfection in the different methods used. No single sign is pathognomonic of pulmonary tuberculosis. A negative sputum is of no assistance in the diagnosis and does not mean that tuberculosis does not exist. In tuberculosis without ulceration one hardly ever gets a positive sputum.

Skin tests have proven of some value in our clinics. We have given the von Pirquet test for the last two years in 1,530 children from exposed families, that is families in which one or two members had active tuberculosis.

The following are our results:

Von Pirquet positive, physical negative, 344 or 21.1 per cent.

Von Pirquet negative, physical negative, 798 or 52.1 per cent.

Von Pirquet positive, physical positive, 376 or 24.6 per cent.

Von Pirquet negative, physical positive, 12 or 0.08 per cent.

This shows that 45.5 per cent. of the total number of children examined have given a positive von Pirquet, and 52.9 per cent. of all positive have had positive signs in the chest; while 52.9 per cent. of all examined were negative to the von Pirquet, and of this number only 1.4 showed positive physical signs of the chest.

It is beginning to be recognized that the complement fixation test in questionable cases is of value, and repeated negative findings extending over a considerable period of time show that the individual has been cured or that the disease is not present.

In conclusion, permit me to say that this brief article is intended as a plea in behalf of the tuberculous and pretuberculous patient, and I strongly urge the necessity of a more painstaking search for this ravaging disease in those who are "just a little below par." And finally I wish to emphasize the necessity of using in our examinations all the means that science has placed at our command.

362 Clinton Avenue.

TREATMENT OF INFLUENZA PANDEMICA.*

By Arthur M. Corwin, M.D.,

Chicago.

Out of the recent pandemic disaster with its deluge of clinical material and unlimited opportunity for studying patients in large camps and hospitals, has come a multitude of papers based upon a multitude of observations, good, bad, and indifferent. Some of these are colored by enthusiasm to prove a theory or try out a notion; too many come from surface findings suggesting small experience in such work and inadequate preparation for it. The results are, therefore, contradictory and confusing. They tend to lead him in a circle who tries to digest them in order to draw a conclusion worth while.

The vast number of cases of influenza with or without pneumonia, the evident diversity of type and complications in various localities, the shocking mortality in some groups, the irresistible spread in spite of physicians, nurses, sanitarians, and an alarmed public, the eagerness with which any new treatment was snatched up, all these and other evidences of our ignorance are at hand.

The pandemic has come and gone and we are still in the dark about it. No drugs will prevent influenza or cure it, so far as we know. No serum or vaccine is yet established as specific in its cure or prophylaxis. Its bacteriology is very much involved and baffling; and out of it looms the *Streptococus hemolyticus* as particularly bad and unmanageable. The key to therapeutic failure is the laboratory's failure, through no fault of the laboratory, to find the cause or stumble upon the antidote.

We still grope here as we do in diabetes, in epilepsy, in dementia præcox, in cancer. Conceding the infectious nature of influenza and recognizing the evident power of its contagion, we have quarantined according to most approved methods, only to find that isolation seemed at best merely to delay the spread, not to stop it. The very fact, however, that isolation did check it temporarily is sufficient reason for continued faith in the principle and for stricter application of it. When we consider our gregarious customs of living in cities, our intimate contacts indoors, packed like sardines in our street cars and railway coaches, in our halls, churches, theaters, schools, and homes, is it strange that we fail in our partial measures of segregation?

Diagnosis was too often in these days a matter of snap judgment. The public was frightened, yes, but nonchalant as to precaution. As with common coryza "few think of the thing as serious until it becomes serious." By that time many other people have been exposed and the epidemic is already among the neighbors, traveling fast like gossip. Therefore, effective isolation, though it is the best remedy in sight, is impossible in the present state of our ignorance, prejudice, and carelessness. But, of course, this is no excuse for discouragement or failure to push quarantine to the very limit in the presence of such danger. It is just possible that our own medical profession is largely responsible for the failure of quarantine to do all it might.

To complicate our position the uncertainties of individual immunity are as certain as the menace of

*Read by invitation before Medical Section National Fraternal Congress, Detroit, Aug. 1919.

the individual carrier of this and other contagions. This question of immunity, natural and acquired, is critically important, and yet too little comprehended. We are at sea upon a wide expanse of uncertain danger, and we rely upon a leaky boat, the bravado of fancied robust health and age limits at which contagiousness is supposed to stop.

Here is a virus of high virulence spread probably from person to person and traveling as humans travel. But the virus itself is like the nebular hypothesis, as someone has said, still up in the air. The method of transmission, the period of incubation, the duration of contagion are likewise star dust. "If the virus in question exists somewhere among immune hosts who are the carriers, how long do they continue as carriers, what are conditions and influences that lead to sudden virulence of the persisting virus, if that is the way it operates?" When a disease becomes malignant as did influenza, often striking down a robust individual in heart failure, what reliance upon immunity is safe? With these and similar questions unsettled we must fight influenza as a man fights in a dark room full of enemies. Small wonder that our efforts at prevention were vain and our attempt at cure empiric and haphazard.

The occurrence of the annual epidemics of so-called colds, and our inability to prevent them, is on a par with the spread of influenza. We preach hygiene and sanitary living, we suggest all manner of rules for eating, exercising, housing, and clothing, but do we escape? On the contrary these serious attacks of coryza come trooping on with the appropriate season, weather, exposure, and indoor living. They dodge the barrage of our favorite remedies and we die—or live to catch another cold. Our propaganda against promiscuous spitting, sneezing, coughing, and talking into the face of the other fellow is good stuff. It has made clean living household knowledge and as we think or hope it has wrought untold prevention.

If then we are correct in our belief that influenza and other serious respiratory infections are sputum borne from human to human, it is fair to say that in the presence of a threatened epidemic of these, if every one would put on a well made and properly fitted gauze mask, change it sufficiently, and sterilize it properly, such epidemics would become unpopular. The experiments of George Weaver and others upon the use of masks in contagious disease wards are more than suggestive.

How rudely then are we jolted from our accepted theories by such experiments as those reported in the *Journal of the American Medical Ass'n* of Aug. 2 by Milton J. Rosenau af Boston, to determine the mode by which influenza is spread! Briefly the work was conducted by a large group of officers detailed from the U. S. Navy and the Public Health Service at Gallops Island the quarantine station of the Port of Boston. These 100 volunteers were all of susceptible age, 18 to 30, all well, and each giving no history of having had the disease.

1. Pure cultures of the *Bacillus influenzæ* (Pfeiffer) in moderate amount were introduced into the nostrils of a few of the group—*Result, negative!*

2. To 19 volunteers a very large mixture of 13 different strains of this bacillus, some of which were recently obtained from lungs at necropsy, were sprayed freely into the noses, eyes, and back of the throats, while the volunteers inspired; some billions of these live microorganisms were used on each man.—*Result, negative!*

3. Into the noses, throats, and eyes of 10 volunteers was sprayed 1 c.c. of fresh secretions, washed and swabbed and coughed from noses and throats of those actively sick with the disease.—*Result negative!*

4. Ten others, each received 6 c.c. of a like mixture, more freshly prepared and some of it swallowed.—*Result negative!*

5. Into the noses and throats of 19 volunteers was introduced material from the noses and throats of influenza victims, directly by means of swabs.—*Result negative!*

All of these volunteers received two and some of them three inoculations.

6. From each of 5 donors sick with influenza, in the febrile stage, 20 c.c. of blood was drawn, mixed, and 1 per cent. sodium citrate added; 10 c.c. of this was injected into each of 10 volunteers.—*Result, negative!*

7. Respiratory mucus collected from influenza patients was filtered through Mandler filters which allow ultramicroscopic organisms to pass; 3.5 c.c. of this was injected subcutaneously into each of 10 volunteers.—*Result negative!*

8. Ten volunteers each came into contact with a sick influenza patient. They talked together for 5 minutes, the latter breathed and coughed directly into the open mouth of the former 2 inches away; each volunteer repeated this with each of 10 selected patients; as a result surely there must have been a crop of new patients.—*Result, negative!*

9. Similar experiments were repeated a few months later at Portsmouth Naval prison near Boston. Here 36 hours after exposure the volunteers inoculated came down with fever and sore throat with hemolytic streptococci present. These were birds of another feather. The theory of sputum transmission of disease still holds.

Our wonder is that in the eight experiments negative as to influenza some other virulent germs did not give positive results, as in the ninth. The final word, in that paper, is "perhaps, if we have learned anything, it is that we are not quite sure what we know about the disease."

Prior to the introduction of antidiphtheritic antitoxin which has all but conquered that disease, one was constantly impressed with the inadequacy of our treatment, by the very multiplicity of remedies, each lauded as a cure. The same condition obtained in the treatment of this influenza-pneumonia pandemic.

There was no uniformity of opinion among physicians, as pointed out recently by Herrick (*Jour. A. M. A.*, Aug. 6). His review of the foreign medical press alone showed the following recommendations —take your choice: intravenous injections of camphor oil, camphorated oil and guaiacol, mercuric chloride, hexamethylenamine, diphtheria antitoxin, tetanus antitoxin, colloidal metals combined with antistreptococcus serum, neoarspheramine, colloid gold, collargol, and quinine in large doses. This list is by no means exhaustive of the vain and in many cases absurd suggestions. That very good internist wisely observes that "there should be no

routine treatment according to which certain drugs are given at stated periods. The treatment is expectant, symptomatic, individualistic, though we are apt to forget in the presence of the public alarm which attends such a serious pandemic that a large proportion of patients with influenza do not need a single dose of medicine."

The consensus of opinion from good medical experience and judgment would emphasize the great importance of rest in bed, early begun and maintained well into convalescence—liquid diet and efficient elimination, of course. To use drugs when sedatives, stimulants, and elements are indicated and to use them skilfully is to say in the same breath that no drug is indispensable; a dozen practitioners will get equally good results with different medicines. One or the other derivative of opium on the one hand and of digitalis upon the other are probably the commonest ground upon which the largest number of experienced physicians stand in the symptomatic handling of this affection. It is important to emphasize the danger of phenacetin, aspirin, and particularly antipyrin in this or any other condition in which the heart muscle is weakened. Probably no drugs are so commonly abused as the coal-tar derivatives and their depressant allies, which the profession by indiscriminate and careless use has done so much to popularize.

As to serums and vaccines probably most of us used some preparations of these. And yet a review of the literature of this method of medication, coming as it does from many hospitals, camps, and experience in general practice is bewildering and inconclusive.

That future prophylaxis and cure of influenza and its complicating infections, pneumococcic, staphylococcic, and streptococcic, is to come from this source, few of us doubt. The work of E. C. Rosenow of Rochester, particularly points that way. And when he speaks we are bound to listen. "Averaging all the results obtained," he says, "it appears that the incidence of influenza was about three times as common and the death rate five times as high among the uninoculated as among the vaccinated persons." This is the most authoritative and strongest statement which we have met upon this question.

We personally used a vaccine, put out by his laboratory, upon 60 patients; half of them took the full three injections, 1/6 of them one dose, and the rest two doses each. These patients were of all sorts as to age and sex; half of them were over 40 years of age and, therefore, supposedly immune; the others were from 16 to 38. The fact that none of these people had influenza does not imply that they would have had it if they had not been vaccinated completely or partially. This number is, of course, too small from which to draw conclusions. However, no evidence of harm appeared in any of the series. In case of similar alarm we shall use this vaccine if available in the absence of a better one. The extensive experience of Dr. Rosenow and the faith we have in his word and his work justify this attitude. To refuse to give our patients the benefit of the diminishing doubt is to deny them a square deal.

We are likewise logical in further use of curative serum, particularly convalescent human serum, where a considerable number of patients makes this obtainable. Epidemic or rather pandemic conditions put us at our wits' end.

Both in prevention and cure we are to continue alert to avail ourselves of the leadership of our trustworthy laboratorians. Only by basing our conclusions upon mortality rates in many series of cases, carefully checking up these data by controls, shall we compass this modern method of attack and find the thing for which we still look.

We have after all these words, expressed little more than we said at the beginning in a single sentence, and which we repeat in substance at the end. Treatment of influenza-pneumonia to date is neither definitely preventive nor curative. The ancient rule must still stand, to give Nature the best aid we can by old reliable methods of treating the patient. Experiment with his disease? Yes, under laboratory cooperation. But be sure that such experiment shall not harm him. The death of rats and guinea pigs shall be the barrage behind which lies safety for humans.

HOMOSEXUALITY.*

By C. P. OBERNDORF, M.D.,

NEW YORK

CHIEF OF CLINIC, NEUROLOGY, CORNELL MEDICAL SCHOOL.

THE analytical studies of the sexual histories of cases referred primarily for the symptom of masturbation, reveal frequently the existence of physical and psychical homosexual elements in association with the autoeroticism. Probably very few people reach adolescence without some definite homosexual experience, but it has impressed me that in cases where masturbation has been pursued with unusual persistence the homosexual component has been particularly strong.

Although we have been accustomed to regard masturbation independently of the manifold psychic associations which induce and accompany it, it is really not enlightening to an individual to class him as a masturbator nor does mere classification assist the physician in advising the patient. Similarly the term "homosexual" reveals very little of the psychic difficulties of a person so labelled, notwithstanding the fact that even in recent medical literature and especially in cases with legal complications scant discrimination is made.† "Homosexual" does not indicate whether the condition is constant or intermittent, purely psychic or accompanied by physical indulgence, a matter of necessity or preference, active or passive, and finally, whether it is conscious or unconscious.

As a very satisfactory working basis, conscious homosexuality may be divided into two classes, subjective and objective. From the prognostic standpoint, these two classes are quite different in their response to psychoanalysis. On the whole, I am inclined to agree with Ferenczi (Zur Nosologie der

*Read by title before the American Psycho-Analytic Society in Atlantic City, June, 1919.

†For example, the two cases reported by M. Hirschfeld and E. Burchard, "Two Expert Opinions on the Relationship of Homosexual Women" (H. Gross' *Archiv.* Volume xx) are psychologically essentially as different as two individuals can be.

Maennlichen Homosexualität, *Zeitschrift für Aerztliche Psychoanalyse*, Vol. i.) that subjective (passive) homosexuality in the male and objective (active) homosexuality in the female are sexual intermediary states. These conditions are biological anomalies of development which are often coupled with unmistakable physical signs. Magnus-Hirschfeld and his supporters have recorded very numerous cases of this kind, where pronounced physical characteristics of the opposite sex apparently furnish the dominating influence in the determination of the inversion* There are exceptions, however, to this general classification, for I have encountered, though rarely, passive male homosexuals and active female homosexuals with no secondary physical sex anomalies.

In contrast to these types of homosexuality which have a physical basis, active homoeroticism in the male and passive homoeroticism in the female, are neuroses, and more specifically compulsion neuroses. Psychologically, the unconscious forces impelling objective homosexuality in the male and subjective homosexuality in the female are psychologically very similar. Such persons show no physical sex variations and the deepest strata of the mental content and the earliest traces of memory in both sexes reveal a normal autoeroticism and a normal attitude especially in regard to the libido toward both parents.

Subjective Homosexuality.—Returning to the biological types, when one probes into the early history of subjective male homoerotics, one is apt to find in their rudimentary development stages numerous indications of their inversion, namely an abnormal feminine character. As very young children they may fancy themselves in the place of the mother instead of in the place of the father, as is normally apt to occur. They usually show secondary physical sex characteristics of which they are keenly aware. They long for dresses like the mother's, for her ornaments, and naturally also for her beauty and the caresses she receives. They play with dolls and prefer to dress like girls and these characteristics continue only slightly changed through adolescence. Through both their demeanor and appearance they are apt to be recognized and rebuffed as inverts by their fellows, even early in life.

A case of this kind will be mentioned briefly, not because the type is at all unfamiliar to the physician having even limited experience in this field of medicine, but because it is rather characteristic and demonstrates the limited value of analysis in altering the condition.

The patient, a Scotchman, aged 28, a butler by trade, was a man of considerable intelligence though limited education. Physically he was small, delicate, blond with a high-pitched voice and a markedly feminine appearance. He shaved for the first time at 16 and had a scant growth of hair. He had acquired the habit of shaving the hair from his armpits and from his chest. Naturally, he was readily recognized by the aggressive male homoerotics as a likely sex object.

In investigating his earlier history the patient recounted his attitude in the following terms: "Although I had three brothers and two sisters, I always played with my sisters and never with the boys. At school I never played football nor did I have any inclination in that direction and though I was quite strong physically, I never liked to fight."

At the age of seven he was masturbated by a man in a lavatory, and at ten, subjected to pedarasty. From that time onward he has been continuously in love with one man after another. The sight of nude men greatly excited him but he does not like a "girlish man." Although the patient had occasionally been actively homoerotic, this has occurred only on rare occasions and then under the influence of alcohol in order to secure sex gratification with himself in the passive role.

In his relations with male companions he has acted the part of the loving reformer, the soft and tender idealist, the faithful servitor. He is frequently chosen by women as a confident in their love affairs and is treated as "one of them" because "women seem to realize that I do not want them."

Although since early childhood, he has essayed intercourse at various times as the result of the urging of friends he has been invariably unsuccessful. So far as I was able to ascertain, only on one occasion has had an erection in the presence of the female sex, namely, at the age of ten, but it is questionable whether the stimulus came from the girl. Remarks of this type, "Id rather go to the electric chair than marry a woman" reveal his present attitude, although he is not without a certain feeling of response in the presence of large women in masculine attire.

Aside from his preference in assuming the role of a passive homoerotic, the patient had been an active masturbator, with few fancies. After being under analysis for about three months, the patient decided that he preferred not to attempt to be further altered in his passive homosexuality.

The analysis of such subjective male inverts does not really bring to light many forgotten effects which might be useful in altering the patient's previous relationship to the masculine sex, but even subjective homoeroticism in the male cannot be regarded as a condition entirely hopeless. Inverts of this type are far less apt to seek medical aid than objective male homoerotics but psychoanalysis may powerfully influence the attitude of the patient toward his malady and especially remove some of the urgent neurotic fears which may accompany the inversion. After analysis, such an invert at least feels himself more reconciled to his passive homoeroticism than previously. My experience in attempting to alter the condition through the administration of organ extracts, *e. g.* orchitic substance, adrenin, etc., has been limited but uniformly successful.

Objective Homosexuality.—A very different conception is forced upon one in cases of active (objective) homoeroticism in males or the homologous condition in females, even after a superficial analysis. Objective homoerotics resemble closely typical compulsion neurotics, and swarm with compulsive ideas and compulsive acts and ceremonies which have been elaborated as protective measures. Physically these patients seem to differ in no way from normal men. A penetrating analysis reveals that behind the compulsion exist tantalizing doubts, as well as that incompatibility of love and hate, which Freud discovered to be the basis for all compulsive mechanisms.

The histories of practically all objective male homoerotics disclose that they were prematurely active sexually and in the direction of aggressive heterosexuality. Their Oedipus fancies were always normal and culminated in sexual sadistic plans of assault against the mother or her substitute and

*An extreme example of this kind is Hirschfeld's "Excretion of Spermatozoa from the Female Urethra" quoted in my article on "Sexual Periodicity in the Male," MEDICAL RECORD, July 5, 1913. The sexual periodicity cases are all biologically more or less intermediary sex states.

barbaric wishes of death for the father who was obstructing their desires. Intellectually they were precocious and created in their curiosity a mass of infantile sexual theories. These early tendencies form the basis for their subsequent compulsive thinking. In addition to their aggressiveness and their intellectuality, strong anoeroticism and coprophilia may characterize their constitution.

One finds that in the neurotic type of homosexuality in earliest childhood they were severely punished by one of their parents (strikingly often by the mother) for some heterosexual transgression (such as attempts at unchaste touching of some little girl or infantile attempts at coitus) and at the time of the occurrence (which they were inclined to repeat in imagination) were compelled to suppress a violent outburst of resentment at their reprimand.

Following such an incident they became especially obedient during the latent period of sexuality, which, however, began early. Sometimes one finds they avoided society of girls and women for a long time after the rebuke and associated exclusively with friends of their own sex.

An analysis of such homerotics of a masculine type, who are abnormal only with respect to their attraction to their love object, generally reveals that this type of homoeroticism is really nothing more nor less than the result of a series of compulsive feelings and compulsive acts which spring from the unconscious.

A history, such as is sketched above, preceded the present homoeroticism of a college student, referred by Dr. E. Moschowitz. He is a youth precocious intellectually, and still under treatment. Physically he is somewhat undersized but distinctly masculine.

He recalls distinctly at the age of 4 of having indulged in heterosexual manipulation quite openly on the piazza of a summer hotel with a little girl. At the time he was greatly surprised to discover that the female child possessed less in the way of external genitals than he himself and he therefore bargained with her that she must allow him to touch her more frequently as a compensation for her deficiency. However, the two children were observed and the occurrence was reported to his mother who admonished him severely. Subsequent to this, the interest he showed in male genitals even as a child of six was so undisguised as to attract the attention and solicitude of his father. While he made several attempts to return to heterosexuality during his high-school days, one attempt after another was thwarted through some incident reminiscent of the original mother warning.

In recent years all of his masturbatory fancies have been homoerotic and there have been one or two actual experiences with males older than himself. However, both in his fancies and in actuality he has assumed the aggressive role with his homosexual object and there seems every reason to believe that when his inhibitions are removed he will again become tolerant to the heterosexuality which he reached so early in life.

A parallel history of passive homosexuality in the female, is illustrated in the following case:

A social service worker, aged 39, was referred for intense nervousness and a fear of tuberculosis by Dr. Elizabeth Bruyn of Brooklyn. Here, too, the homosexuality was considered and treated as a compulsion neurosis. During investigation of her condition, it developed that the patient had somewhat prematurely progressed to heterosexual stages and that following incest with her brother at the age of 10, as a result of which she thought herself impregnated, she began masturbation in a mild form. Notwithstanding the intense worry which the idea of pregnancy had caused her, she gradually drifted back again to normal heterosexual associations. At 25, while seated on the lap of one of her young men acquaintances, penetration occurred with rupture of the hymen. This so mortified and terrified her that she again began to avoid companions of the opposite sex and soon came under the sway of active female homoerotics.

For the ten years prior to the onset of her neurosis, she had been living with another social service worker of a decidedly masculine personality, in the relationship of a wife. Her consort paid her board, gave her many presents (including a ring) and willingly acquiesced to the patient's working spasmodically, while she contributed to her support. However, the patient did not remain loyal to her mate and had had several minor and one intense love affair with other women, but had invariably assumed the passive role. During this period of homosexuality, her masturbation became more intense, with fancies of a male consort and herself in a passive role.

After a violent struggle with her conscience and many self-reproaches for her infidelity to the lover to whom she felt morally obligated, she developed a neurosis. The physical symptoms at the time, namely, gagging, vomiting on arising and abdominal cramps, and the mental symptoms, fear of being alone, fear of insanity, etc., seem to have been quite overshadowed by a hacking cough and the expectoration of phlegm. At all events, because of her tuberculosis which was evidently very mild, she was sent to a tuberculosis resort where she worried so over her pulmonary tuberculosis (it is likely that such actually existed) that the physicians at the sanitarium suggested that she return to New York.

While the above description outlines the salient features in her history, it does not take very complete cognizance of the host of impulses and resistances which had tormented the patient until she found her temporarily satisfactory compromise in passive homosexuality. It is cited as an instance where the retrogression to the homosexual stage unconsciously resulted from a fear of heterosexuality. Following an analysis which lasted a year, the patient has been able to relinquish her homoerotic relationship and has ceased masturbation and is now one of the most proficient workers in her particular field of service.

It has not been my intention to exalt autoeroticism or homosexuality nor in any sense to belittle the grave social consequences which result from such abnormalities. While homosexual friendships may be instigated by genuine affection and at times exist even without any physical contact, there are others, far more numerous, characterized by obliquities of the most sordid type. And yet, if we take it for granted (and I think we must) that most individuals would prefer to conform to normal standards rather than deviate from them, it is evident that we must consider homosexuality as a disease (the one form of compulsion neurosis, the other a biological anomaly) rather than a crime. In cases where the biological manifestations are extreme, as in well developed eunuchidism, the idea of regarding the condition as criminal does not occur.

Like insanity, homosexuality calls for legal criminal restrictions principally when there has been some direct and uninvited infringement upon the person of another. This, as is well known, concerns only minors as a rule. However as a disease, homosexuality warrants the attention of physicians dealing with abnormalities of conduct quite as much as autoeroticism,with which it is so often associated. As a general rule the homosexualist is not so profoundly diseased mentally as a person of the autoerotic type which is so prone to lapse into the discouraging precox states. Yet, precisely for this reason, he is a greater menace to the psychic health of the community, just as the walking typhoid offers

greater dangers of infection to others than the bedridden one and the half-intoxicated man has greater possibilities of doing violence than the one who lies in sodden stupor.

HAMMER TOES.

By NELSON A. LUDINGTON, M.D.,

New Haven, Conn.

The following case is recorded so as to be available to any one interested in the etiology of hammer toes, and incidentally to afford an opportunity to call attention to the fact that there is a definite method of treatment, and amputation is no part thereof.

Laura S., æt. 63, widow, housewife, nationality American. Her complaint was of deformity of her toes, with painful corns on the deformed toes.

Physical examination revealed the condition shown in the accompanying illustrations. There was no deformity or contracture in the hands.

The father had developed bilateral hammer toes in middle life. Attributed the deformity to wearing narrow-toed shoes. One elder sister developed one hammer toe at about 50 years of age; she never wore narrow-toed shoes.

The patient first noticed the deformity in the left foot at 56 years of age; that in the right foot at 60 years. She has never worn either narrow-toed, high heeled, or short shoes. Has attacks of painful contraction of the extensor tendons, which is relieved by removing the shoes and manipulating the toes by flexion and extension at the interphalangeal jonits, and by flexion alone at the metatarsophlangeal joint.

The patient was willing to have the toes amputated under local anesthesia; but was unwilling to submit to or "putter" with other methods, as she had on three or four occasions consulted physicians, and they had all been of one mind, namely, "amputation was the only cure."

Briefly, the pathology of hammer toes is a contraction of the ligaments around the joint. The tendons play a minor role. Simply dividing the tendons fails to restore the position. The ligaments

Fig. 1.—Bilateral Hammer Toes.

must be elongated either by stretching, or by cutting, or both.

In mild cases, manual correction of the malposition twice daily with the wearing of broad-toed shoes will correct the deformity. In the more advanced grades, in addition to the foregoing, an aluminum sole plate, having an extension underneath the affected toe is worn at night. The affected toe is strapped to the extension. The toe may be restored at once to normal position by forcible manual manipulation, and the sole plate employed

Fig. 2.—Hammer Toes. Plantar view. Note abduction deformity of hallux. Comparison between right and left shows progress of deformity in four years.

to maintain the result. For this an anesthetic is required.

Subcutaneous division of the lateral and capsular ligaments, and, if need be, the tendon also, permits the toe to be restored to its normal position. Following this operation the sole plate is also used.

Complete resection of the joint by lateral incision may be resorted to in an extreme case where other methods have failed.

Amputation is unnecessary. It impairs the mechanics of the foot. It augments the ever-present tendency of the great toe toward outward subluxation, and so increases the probability of the subsequent formation of a bunion.

Prevention of Influenza.—Fifty orphans in an institution escaped the wave of influenza which was active last October and isolation may be excluded as the cause of the immunity. The children all received a mixture of quinine, salicylate of soda and quinquina or powdered bark. The children also escaped two subsequent waves or local outbreaks and Camescasse is compelled to differ with those who have decided against prophylactic precautions.—*Bulletin général de thérapeutique.*

Fate of Gravidæ with Heart, Lung, and Kidney Disease.—Hüssy gives the following figures from the Basle Clinic. The toal number of confinements for a given period was 15,352, of which 35 women suffered from organic heart disease, over one-half presenting mitral stenosis. One woman died during gestation and 3 primarily as a result of delivery, while 6 others died later, the exact mechanism not being given. The total mortality to date was, therefore, 10. In 19 cases pregnancy and labor did not prejudice the patient's condition at all and in 7 others but slightly. In 14 cases the women were seen to grow worse during pregnancy. In 10 patients therapeutic abortion was performed. The figures show considerable overlapping. The total number of tuberculous women received at the midwifery clinic was 76. There were 14 deaths during gestation while in 14 cases therapeutic abortion was performed. Five died after delivery and 8 as a result of the same at a more remote period. Forty-eight went through gestation and labor without prejudice of any kind. The total number of renal cases was 15. There were no deaths in gestation, but 3 after delivery. Seven went through pregnancy and labor intact, while 3 were made worse but survived.—*Correspondenz-Blatt für Schweizer Aerzte.*

MEDICAL EDUCATION.

ONE point strikingly demonstrated during our military experiences was the unsatisfactory condition in which medical education in the United States found itself. The recognition of this situation is evidenced in a number of papers which have appeared during the past year. Those who have occupied positions that demanded the review of a large number of medical officers have expressed their surprise in finding such a high percentage of them wretchedly equipped in those fundamentals which are essential for the recognition and treatment of disease conditions. It is no concern of ours that a somewhat similar situation confronts teachers of medicine in European countries. But it is all-important that educators in this country recognize the direction in which we are drifting and put forth every effort to improve our methods. It is regrettable that the chief danger lurks behind the admirable title of "scientific medicine." Surely no one wishes to minimize in the least the many important gifts which real science has made to the advancement of medicine. But the devotees of what may be called "pseudoscience" have confused the issues until it is high time that we call a halt and seriously consider where we are and in what direction lies the road upward.

In former times there existed what is now known as the "old time general practitioner," a man of keen observation who was able to benefit by his experience and who, without microscope or laboratory or sphygmomanometer, was able to recognize the aspect of disease chiefly, we are fond of saying, by "intuition." But workers in the laboratories discovered certain facts and to-day there seems to be arising the danger of the development of a class of medical men who are unable or unwilling to diagnose malaria unless the parasites are found in the blood smear, or pulmonary tuberculosis unless tubercle bacilli can be demonstrated in the sputum. Science has made important discoveries but pseudoscience has filled our ears and our literature with a multitude of complex laboratory methods for the detection of certain symptoms until the laboratory has become deified and its brilliancy has blinded us to the common means that lie near at hand, the proper use of our experience and our powers of observation.

Sir James Mackenzie has observed this trend in medical affairs and has been led to write out his views for the benefit of all those who will read. His book* is one that should be read carefully by every one concerned in medical education. He enunciates a number of principles that certainly appear to be incontrovertible and yet, just as certainly, they are not followed in many of our medical schools. He points out that "a teacher of practical matters must be one who has experienced what he teaches." But there is a wide and influential circle here who advocate the greatest possible extension of what is known as "full time instruction." In the logical development of the full time method general practitioners will be taught by men who are not and possibly have never been general practitioners. The avowed aim of the medical school is to turn out general practitioners and yet the general practitioner is not consulted when methods of instruction are to be modified. Much time is still wasted by the student who takes notes of a lecture whose subject matter is amply discussed in available text-books. Mackenzie claims that "the individuals, conducting an investigation, should have the opportunity of seeing disease in all its phases and of observing the symptoms it produces." And yet the great bulk of our research is carried on by laboratory workers who never have this opportunity. He points out the inequity and inefficiency of our present method of examinations and calls for the protection of the student against the unfair examiner. He shows the manner in which the student is influenced to become either a "therapeutic nihilist" or else an indiscriminate user of a vast number of drugs, each of which he believes to have some special and peculiar action, by the observation of the prescriptions of his teachers. In comment upon the splitting up of medicine into numerous specialties, he points out why the specialist is apt to be unsatisfactory as a teacher.

It is naturally impossible to cover in a few lines a subject of this size, but one is made aware of the necessity for a radical change in our methods. At the present time it is the policy to cram our medical students as full of facts, or what we believe to be facts, as is possible in the time allowed in the medical course. If it can be managed to inculcate ideas as to how these facts are to be used and how one is to reason from or toward them, so much the better, but the main idea is to load them up with facts. Methods of obtaining results in the laboratory also occupy a good part of the curriculum. Would it not be better if our main purpose were to instruct the student how to think, how to observe the sick patient, how to study symptoms and to benefit by his experience, and to

*The Future of Medicine. By Sir James Mackenzie, F.R.S., M.D., Consulting Physician to the London Hospital; New York: Oxford University Press, American Branch. 1919.

add to that as many demonstrated truths as the remainder of our time would permit? Tell him where to go in the literature for his information and make him familiar with the real scientific classics. If he learns to reason things out for himself and is not content to have his mental pabulum administered with a spoon, he will not find himself at a loss in any situation. It is a critical time in our lives and we would be wise to ponder these things well.

A NEW "DISEASE": AFTER-DINNER SPEAKING.

THAT there are enough diseases in the world to-day goes without saying and that they are important enough to hold our attention and cause us labor in arriving at correct diagnoses need not be emphasized here. Were a pre-Civil War physician to return to make comparisons between the number of diseases that "bothered" him and the number which are to-day causing new thought in the medical profession, he no doubt would be sadly perplexed and not for long would his gentle spirit remain with us. And the same disturbance of thought would be apparent were a physician of a later decade to return, and of succeeding decades, let us say, until the birth of the twentieth century. Just as the dictionary grows each year on account of the new words which human ingenuity evolves, so in a much lesser degree so-called new diseases are brought into light, the qualificative "so-called" being used by us lest some medical historian should object to its absence and reprimand us severely for not knowing that in 39 B. C. the disease was well known. And even the new "disease," "After-Dinner Speaking," should rightly be qualified by the term "so-called," since it has been with us as a scourge for hundreds of years, though never before classed as a disease.

In the *Atlantic Monthly* for October, Burgess Johnson of the English Department of Vassar, writes entertainingly on the subject, and declares his modesty by expressing his doubt as to whether after-dinner speaking is a disease by using the interrogation point. But though he starts out gingerly as if he were treading on ground that was not his proper sphere, he soon enters bravely into the subject and affirms that all after-dinner speakers, who talk for a considerable length of time, who are oblivious to the impatience of their audience, as illustrated in shuffling of feet, yawns of unusual dimensions, and the shoving of plates aside, or the constant toying with knives, forks, and spoons, are practising autohypnosis or rather are the victims of it on account of their being afflicted with hysteria.

The refined explanation given by the author in the *Atlantic Monthly* is of the sort that makes for excuses for an infliction, and although considerable ridicule is visited on the perpetrator of an unceasing flow of anecdotes and a multiplicity of words, which invariably follow a statement that the indulgence of the diners is kindly requested for a few remarks which will cover only a few minutes, the fact that autohypnosis is stated as the solution of why thousands upon thousands of men have been bored to exasperation, is wrong; for no doubt those who will read the article will change their opinion of the after-dinner speaker, will be kindness itself to him, and whenever anything of a truculent nature is said about him, will cry out against the denunciation because the speaker cannot help being a bore, for is he not afflicted with an incurable disease? Hence the day is not far off, now that so authoritative a magazine has given voice to the matter, when some medical man, grown weary of his typhoid fever cases, his pneumonia cases, his "common cold" cases, will launch into cold medical print the symptomatology and treatment of this new disease.

As medical men we are loath to accept, as a disease, the infliction visited on us by after-dinner speakers, and as medical men we should in one voice denounce Burges Johnson for having put into the minds of thousands of readers thoughts which are inimical to the science of medicine. As was stated above, the number of diseases which are with us to-day should suffice for some years to come without adding another to the list, especially when the "disease" is an excuse for a crime against our patience, our amiability, our good-naturedness! These qualities are not always with us, even at public dinners where they ought to be in force—the meal, no matter how poorly cooked, should awaken them; and less often are they characteristic of us when our sense of duty whispers to us we must go to the meeting of our respective medical society where several papers of great interest are going to be read. But despite a somewhat distant semblance to the triumvirate—patience, amiability, and good-naturedness—a fact which must be apparent to the speaker at once, there is seldom any consideration shown us for being human, perhaps too human. Papers of interminable length are read in tones that would be soporific if our nerves were not unstrung, and line after line is read or spoken until reiteration is worn so threadbare that if it had a mentality it would surely cry out with pain. The reader or speaker cares not a whit whether his voice is entertaining or the opposite, cares not a whit whether a number of men edge toward the full limit of their chairs and are about to topple over, cares not a whit whether a minority or a majority in the audience is demonstrating a deep interest in the ceiling, the floor, or the window-frames. Nothing disturbs his equanimity—he is a little David who is going to vanquish this somewhat turbulent mass before him—the giant Goliath. And yet can one attribute his indifference to the somewhat belligerent attitude toward him to autohypnosis induced by a state of hysteria? An everyday sort of man, who has never allowed his thought to be influenced by the higher flights of oratory, who knows nothing of hyperboles or attenuated similes, whose both feet are always planted on the

earth and whose eyes drink in only the prose of life, practising or inviting autohypnosis! We know him to be respectable and a hard worker, and we know him to be above deceit. And we also know that he is not "diseased" in the way Burges Johnson would have us to believe. Hence our criticism of him will continue, with no sympathy, but with a feeling that if he would only shake off his humdrumness he might arrive at a stage in his development when he would realize the many uncomfortable moments he has given us by his inattention to brevity, to consciousness, and to voice culture.

TREATMENT OF QUININE-RESISTANT MALARIA WITH X-RAYS.

In those trying cases of malaria in which quinine seems to have no power to bring relief, the usual custom has been to resort to arsenical preparations, with occasional success but more commonly failure. Recently Pais, writing in the *Annali d'Igiene* (June 30, 1919, xxix, 6) has tried the effect of the *x*-ray in this condition, and publishes the results of over 3,000 experiments along this line. His idea has been to rouse the body cells by radiation with small dose. Thus the stimulation of the blood-making organs should enable the organism to put up a better fight against the plasmodium and its effects. We have the empirical fact to start with that the rays are able to modify favorably the fever curve. It may also be shown that with high doses the disease is unfavorably influenced. Experiments show a relative constancy in the response of the malaria-infected organism to doses of rays of the same strength, the action differing from that of quinine, which shows no such constancy. There is some difficulty in the measurement of minute doses of the rays; and the need of an elaborate technique will make progress along these lines slow. Prolonged radiation—extending over 3 or 4 hours per session—would appear to produce certain results which, however, are not calculated to appeal to the public when measured against the outlay of time and the expense.

According to the clinical expression of the disease the sensibility of the organism to the rays may vary. Thus if the attack is hyperacute the sensibility to the rays is high, and the therapeutic doses small. At the other extreme there are cases termed by the author radioresistant. These cases are not benefited by quinine but the term radioresistant is used only in a relative sense, for the doses required are larger than in the preceding. Thus far the author has rayed the spleen chiefly and has studied the subsequent blood pictures, the state of the plasmodium, the fever curve, and splenic tumor. The erythrocytes are first diminished, then increased to the normal. The disappearance of the parasites from the blood is slow but apparently sure. The state of the spleen seems at first aggravated, but in a short time improvement is noted and within a few weeks it undergoes involution to the normal size.

CONCERNING LAZY CLINICIANS.

The profession considers itself more and more fortunate as instruments and means of precision become more and more available. We see this particularly in hospitals, where *x*-ray or electrocardiograph, blood-urea, or stool culture, can be had by simply writing an order. Certainly the army showed itself ready to make use of the many laboratory aids to diagnosis. At least where practicable, as in the base and general hospitals, the medical department spared neither effort nor expense in equipping the various laboratories with adequate materials and personnel. And as elsewhere, the results fully showed the wisdom of such a course. But how often, especially when wards were a little crowded, were *x*-rays and Wassermann tests ordered after only a cursory examination of the patient, made in the knowledge that the "lab would check up"—thus passing the diagnostic buck to the laboratory man! How often, among the "better trained men" of today, we see a surgeon give an "acute abdomen" a rough pawing over, and then haggle with an interne over a hundred leucocytes more or less in the blood count! How often the scar of an old chancre is missed and the diagnosis of syphilis left to complement fixation. There is a story, popular in one of our hospitals, that a man was rushed to the hospital after having drunk poison. One attending physician urged the staff to hurry and obtain blood for a carbon dioxide test. Another ordered them to wash out the man's stomach, thus endeavoring to save the laboratory from the complete victory of performing an autopsy.

It is time to put the laboratory in its place, even though we give it a high place, and then let us not be above noticing the pectoral rigidity, the few râles, the diminished expansion. Let us not miss the Argyll-Robertson pupils in our anxiety over the spinal-fluid Wassermann. Let us not miss the air-hunger in our zeal for the alveolar carbon dioxide. Let the students be taught "desert-island diagnosis," not to make them any less scientific, but to make them less lazy and dependent. At least let not the ghosts of Hippocrates and Laennec rise to scorn us as milk-fed clinicians.

The Empirical Origin of Therapeutics.

The introduction of rationalism and science into the cure of disease is of such recent date that many a year must elapse before we can regard this innovation as actually dominant. Even the herbs, the simples, which were first used empirically to modify disease, were a part of the armamentarium of the magician and indispensable for his incantations. The humblest garden weed was often, according to the latter, more potent from the standpoint of conjuring the dead than the expensive and gorgeous exotic. Many of the earliest remedies for disease were of the same type and from the scientific viewpoint quite inert. Yet they were recommended by the earliest of the rational physicians, equally with drugs of toxic powers. Medical treatment, including the use of drugs, was often prescribed through

methods of divination. Three recent numbers of *Janus* (1919, xxiv, 6, 7, and 8) contain an article upon these subjects by Saintyves, from which it appears that even the rationally inclined Greeks of the age of Hippocrates and later mixed reason with divination. Iatromancy, so-called, was in fact in universal use; and while medicines were usually prescribed they were often enough suggested by dreams. Pliny relates that a soldier with hydrophobia, an incurable malady, was saved by using an infusion of wild rose root suggested in a dream. Alexander, when one of his favorite generals was ill of an infected wound, dreamed that an unknown but precious root cured him. He described the plant of his dream, which the natives had no difficulty in identifying and supplying. The juice of the root proved to be efficacious. In similar cases cited it appears that a plant was the choice of remedy, for in none of the dreams was any other resource mentioned, although bathing in certain springs and numerous other agencies have been prescribed by dream personages. To stimulate dreaming of this character the sick were allowed the privilege of sleeping in temples and eventually in Christian churches and Moslem mosques. Hence the first use of drugs was very largely of a mystic or symbolic character, with little regard for physiological action or for any popular repute in healing. If one could trust the laboratory healers and therapeutic nihilists of the present day, one might conclude that the users of drugs even now are but little more scientific than their predecessors of two or three millennia ago, but fortunately we are swinging clear of the nihilistic tutorage, and are coming once more to give drugs for their effects on man and not on the frog.

Testicular Grafts and Surgical Opotherapy.

The *Archives Médicales Belges* of July 7, 1919, lxxii, 7, contains the first professional account we have seen of the sensational experiments in testicular grafting by Voronoff, which received such wide newspaper publicity. The article is a joint review by Voncken, which opens with an account of experiments made by Lydston years ago. The American surgeon receives full credit for priority in this field, but close behind him came the Dutchman Steinach, who, in June, 1918, reported the cure of a homosexual by implantation of a testicle. In this case the subject does not seem to have been a true invert but rather a pseudohermaphrodite with sex confusion. The homosexual component was due to the gonads, for the apparent testicle proved to be more of an ovary than a male gonad, and the grafted testicle caused the disappearance of both the homosexuality and hermaphroditism. Rohleder, as early as 1917, had suggested the grafting of testicle as a cure for true inversion, but it does not appear that any cases were reported. Voronoff did his work in the laboratory of the Collège de France and reported his results before the last session of the French Congress of Surgery. But the only experiments mentioned by Voncken were on animals—old he-goats and rams. Nothing is said of old men or chimpanzees. It is, of course, possible that Voronoff has published other work at a later date, but the only experiments made on man which receive mention in the article are those of Lydston and Steinbach with an account of a case by Leichtenstern during the war in which a cryptorchid testicle was implanted in the scrotum of a soldier who had been castrated by a wound. The result was excellent.

News of the Week.

Siberia Menaced by Typhus.—A cable message from Tokio to the Associated Press, under date of Oct. 14, reports that advices from Omsk say that Siberia is threatened with one of history's great typhus epidemics. According to Colonel T. B. Teusler of the American Red Cross, the total of typhus cases among the Siberian troops since Jan. 1, 1919, is 120,000. Fresh cases are occurring at the rate of 1,000 daily. All available hospital resources for disinfection are overwhelmed and the fever is rapidly spreading among healthy soldiers and the civil population. The sanitary conditions, according to the reports, are so frightful that unless the American Red Cross can furnish relief the death toll this winter will be beyond anything heretofore known in Siberia and Russia.

The Needs of Polish Hospitals.—The American Red Cross states that ether, rubber goods, and surgical dressings are the greatest needs in Polish hospitals. Surgeons are being forced to use cotton gloves in operating or else operate with their bare hands. In the military hospitals of Crakow gauze is washed and rewashed many times. In the city of Crakow there are six military hospitals with from 650 to 1,800 beds each, and in the surrounding district are sixteen military hospitals with a total of 10,106 beds. There are also eight civil hospitals with a total of 2,500 beds. Most of these hospitals are overcrowded and turning patients away. In some wards there are said to be two patients in a bed. The Red Cross relief work in Poland is under the direction of Dr. A. J. Chesley of Minneapolis, Minn.

New York University Medical College Enrolls Women.—For the first time in its history the New York University Medical College has enrolled twenty women. They are on exactly the same footing as the men, attending the same classes and working in the same laboratories and clinics.

Report on After-Care of Poliomyelitis Cases.—The New York Committee on the After-Care of Infantile Paralysis Cases has just issued its annual report, which shows that during the year just ended the committee has taken care of 8,253 cases. Most of the children who have had regular after-care have shown great improvement, and many have been cured. The committee finds, however, that there is still a great deal to be done. A survey now under way indicates the necessity of a complete record of cripples, additional clinics, and increased means of transportation, also the development of field agencies to assist those in need of orthopedic assistance.

Doctor Quits Former Emperor.—Dr. Foerstner, private physician of the former Kaiser Wilhelm, has quit Amerongen because he has found it impossible to support his family on the meager salary in German marks paid by the former Emperor. Dr. Foerstner has returned to Berlin to resume private

practice, and a military surgeon, Dr. Jenner, has arrived to serve temporarily.

Dermatological Society Celebrates Anniversary.—The New York Dermatological Society, which was founded in 1869 and is the oldest dermatological society in existence, celebrated its fiftieth anniversary with a dinner at the Yale Club on the evening of November 8, 1919. Dr. George Henry Fox, one of the oldest members of the society, made an address in reminiscent vein.

New York Makes New Health Record.—The records of the New York Health Department given out on November 6 show that the average death rate since May 17 has continuously been below 12 for each 1,000 of the population, a rate unprecedented in the history of the Health Department. The average death rate for the twenty-four weeks preceding November 2 was 9.54 per 1,000 of the population. The death rate for the first 24 weeks of this year was 12.80 per 1,000 as against a rate of 16.51 for the corresponding period of 1918, a decrease of 3.71 points.

St. Mary's Hospital, known during the war as Army Base No. 1, in Hoboken, has been vacated by the military authorities and returned to the Sisters of St. Francis.

Commission Appointed to Study Influenza.—The Metropolitan Life Insurance Company has provided resources to carry on investigations into the cause, mode of transmission, and treatment of influenza and its complications. A commission has been appointed consisting of G. W. McCoy, Director of the Hygienic Laboratory, U. S. Public Health Service; Dr. W. H. Park, Director of the Research Laboratory, New York City Department of Health; Dr. Lee K. Frankel, Third Vice-President of the Metropolitan Life Insurance Company; Dr. A. S. Knight, Medical Director of the Metropolitan Life Insurance Company; Dr. M. J. Rosenau, chairman, Professor of Preventive Medicine and Hygiene, Harvard Medical School; Professor E. O. Jordan, of the University of Chicago, and Dr. W. H. Frost, of the U. S. Public Health Service. Work has already been begun in Washington, New York, Boston, and Chicago, and may be extended to other places as occasion arises. Studies are now being made on the prophylactic value of vaccines against influenza, common colds, and pneumonia, and laboratory researches are being conducted to determine the cause of these infections. A special study of the flora of the upper respiratory tract in health and disease is to be made. Co-operation and suggestions are invited from health officers and others interested.

Pediatric Societies Meet.—The Annual Joint Meeting of the New England Pediatric Society, the Pediatric Section of the New York Academy of Medicine, and the Philadelphia Pediatric Society was held in Philadelphia November 8, 1919. The day was spent in visiting institutions and attending clinics and in the evening William Curtis Farabee, Ph.D., Curator American Section of the University Museum, gave an illustrated talk on "Child Life Among the Tribes of the Amazon Jungles." The entertainment of the day included an automobile ride through Fairmount Park and a dinner at the Hotel Rittenhouse.

Long-Lived Microbes.—In a paper recently read before the Academy of Sciences in Paris, Prof. Yves Delage described studies made by Dr. Gallipe, who is credited with finding in century-old paper microorganisms still living. According to report these organisms had survived a temperature of 248 degrees. The papers in which these microbes were found belonged to the fifteenth and eighteenth centuries. Dr. Gallipe has also found organisms in fragments of Chinese manuscript dated before the invention of printing, and these organisms were still capable of cultivation.

Medical Society Elections.—The NEW YORK AND NEW ENGLAND ASSOCIATION OF RAILWAY SURGEONS, at its twenty-ninth annual meeting held in New York October 20, 1919, elected the following officers for the ensuing year: *President*, Dr. William B. Coley, New York City. *First Vice-President*, Dr. J. F. Black, White Plains, N. Y.; *Second Vice-President*, Dr. Donald Guthrie, Sayre, Pa.; *Treasurer*, Dr. James Hamilton, Rutland, Vt.; *Corresponding Secretary*, Dr. George Chaffee, Binghamton, N. Y.; *Recording Secretary*, Dr. J. H. Reid, Troy, N. Y.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION, at its forty-fourth annual meeting in Louisville, Ky., October 22, 1919, elected the following officers for the ensuing year: *President*, Dr. Frank B. Wynn, Indianapolis; *First Vice-President*, Dr. C. W. Dowden, Louisville; *Second Vice-President*, Dr. Frank Smithies, Chicago; *Secretary*, Dr. Henry Enos Tuley; *Treasurer*, Dr. S. C. Stanton.

Gifts and Bequests.—The Rockefeller Institute for Medical Research announces that John D. Rockefeller has added $10,000,000 to his previous gifts to that institution. The addition of this gift will not result in any considerable extension of the work of the institute but will simply meet a deficiency, since the recent cost of the work has exceeded the income from the endowment fund.

Under the will of Louis J. Weil of New York, Mt. Sinai Hospital receives a bequest of $5,000 to found a bed in memory of his father. The Montefiore Home and the Home for Aged and Infirm Hebrews each receive $500.

Under the will of the late Mrs. Margaret E. Zimmerman, the New York Nursery and Child's Hospital receives a bequest of $200,000 and the General Memorial Hospital $50,000.

Obituary Notes.—Dr. ALEXANDER BLEEKER LEGGETT, a graduate of the College of Physicians and Surgeons, New York, in 1858, died at his home in Babylon, L. I., on November 6, aged 84 years.

Dr. ALBERT C. H. BARGE, a graduate of the Long Island College Hospital, in 1911, and assistant gynecologist to the German Dispensary, died of diphtheria at his home in Astoria, L. I., on October 23, aged 35 years.

Dr. EDMUND B. FRYE, a graduate of Dartmouth Medical College in 1879, died at his home in Wellesley Hills, Mass., on October 23, aged 63 years.

Dr. HORACE P. MACKETCHNIE, a graduate of Bellevue Hospital Medical College in 1879, died at his home in Somerville, Mass., about October 17, aged 78 years.

Dr. J. FREDERICK SMITH, a graduate of the College of Physicians and Surgeons in 1882, died from pneumonia at his home in New York City on October 18.

Dr. WILLIAM ADAM SEIBERT died at Easton, Pa.,

on October 7 at the age of 61 years. He was a graduate from the Boston University School of Medicine in the class of 1885. He was a trustee of the State Hospital for the Insane at Rittersville, Pa.

Dr. CHARLES W. FOX, of Philadelphia, died at York Harbor, Maine, on October 8 at the age of 76 years. He was graduated from the Long Island College Hospital in the class of 1865.

Dr. ADOLPH L. BARCUS died at Philadelphia on October 12 at the age of 58 years. He was graduated from Jefferson Medical College in the class of 1891. He was a member of the Medical Society of the State of Pennsylvania, of the Philadelphia County Medical Society, and of the American Medical Association.

Dr. SIMON M. DUBIN died of heart disease at Philadelphia on October 15 at the age of 53 years. He was graduated from the University of Berne, Switzerland, in the class of 1896.

Dr. HENRY K. OLIVER, who retired from the practice of medicine some years ago, died at his home in Boston on October 26, on the eve of his ninetieth birthday. Dr. Oliver was graduated from the Harvard Medical School in 1855, and then studied for two years in Paris and Vienna. He served as medical inspector of camps in McClellan's army during the Civil War. In 1868 he was appointed visiting physician to the Massachusetts General Hospital and later lecturer on diseases of the throat at Harvard Medical School. He was the anonymous donor of several hundred thousand dollars to the new department of hygiene of Harvard Medical School, a fact that became known only after his death. This department will henceforth be known as the Dr. Henry K. Oliver Foundation.

Obituary.

FLOYD MILTON CRANDALL, M.D.,

NEW YORK.

Dr. FLOYD M. CRANDALL of New York City died November 19, at the age of 61. Dr. Crandall was graduated from the Medical Department of the University of the City of New York, in 1884. He was a lecturer on diseases of children and later adjunct professor of diseases of children in the New York Polyclinic; surgeon, New York Skin and Cancer Hospital, and consulting physician to the Infants' and Children's Hospitals. He was an active member of the American Medical Association, the Medical Societies of the State and County of New York, and the American Pediatric Society. He was assistant editor of the New York *State Journal of Medicine*, and was a frequent contributor to medical literature.

RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

Dr. RICHARD COLE NEWTON, formerly a surgeon in the army, died at the Mountainside Hospital, Montclair, November 13, 1919, a few hours after a stroke of paralysis. He was born in Roxbury, Mass., June 23, 1851, but had lived in New Jersey since he was six years of age. He was graduated in arts from Harvard University in the class of '74, and in medicine from the College of Physicians and Surgeons, New York, in 1877. After leaving the army, in 1880, Dr. Newton entered the practice of medicine in Montclair, serving at one time as a member of the New Jersey State Board of Health. He was a member of the Essex County Medical Society and of the Associated Physicians of Montclair and vicinity. During the world war he was a member of a local draft board. Dr. Newton made numerous contributions to medical literature.

WILLIAM G. BISSELL, M.D.,

BUFFALO, N. Y.

Dr. WILLIAM G. BISSELL, well known as a bacteriologist and expert in matters of sanitation and public health, died at his home in Buffalo, November 13, at the age of 49. Dr. Bissell's preliminary education was received in the public schools of Lockport, N. Y., the city of his birth. He was graduated in medicine from the University of Buffalo in 1892, following which he specialized in bacteriology and other phases of laboratory work, taking courses in various laboratories, including that of the Army Medical School, at Washington.

For twenty-five years Dr. Bissell was director of the laboratories of the local Health Department, and was president of the New York State Sanitary Officers' Association. He was connected with various organizations in the capacity of health and sanitation expert. He also served as president of the State Board of Medical Examiners. For twenty years he was surgeon of the Seventy-fourth Regiment, New York National Guard, retiring in 1914 with the rank of Major. He served during the world war as Lieutenant-Colonel, Medical Reserve Corps. He made numerous contributions to medical and scientific literature.

Correspondence.

LIPOVACCINES.

A REPLY TO SURGEON-GENERAL BLUE.

TO THE EDITOR of the MEDICAL RECORD:

SIR:—In a letter dated October 17 Dr. Blue sends me his correspondence published in the MEDICAL RECORD, accompanied by a letter in which he states that my article contained "a number of misstatements." In the published letter headed "Correction of Erroneous Statements in the *Chicago Daily Tribune*," he describes my article "as so misleading." He brands two of my statements as misstatements. A third statement made by me he pronounces correct in his letter to me. The several other statements are not touched upon.

First, let me briefly discuss the statement relative to the use of lipovaccines by the army. Frankly, I did not know of the War Department March circular on lipovaccines until I received Dr. Blue's letter. However, I now have a copy of the circular before me and I find the facts are not in full accord with Dr. Blue's statements. I refer to "S. G. O. 444.2, Surgeon-General's Office, Mar. 12, 1919," signed C. R. Darnall. Dr. Blue says: "The fact is, the army discontinued distributing lipovaccine some months ago and withdrew that which was outstanding." The circular reads: "Lipovaccines were

adopted as a war measure on account of their obvious advantages and have served their purpose. The technique of manufacture, however, needs further improvement and the duration of their protective power as compared with that of saline vaccines needs further investigation. Saline vaccines, therefore, will be used as a routine and lipovaccines will be reserved for emergencies."

The second charge of error is flimsy. My article related to measures of control of influenza. Among other methods I referred to the use of vaccines. Six paragraphs were given to discussion of vaccination. A part of the discussion of vaccines was devoted to lipovaccines. In giving the evidence for vaccination I cited the two army experiments inadvertently referring to the work at both Upton and Wheeler as having been done with lipovaccines. As is well known the vaccination at Wheeler was with lipovaccines, those at Upton with saline vaccines.

My articles contained replies to eleven questions. Dr. Blue dissents from statements in connection with two. How well he has made his points the reader may judge. How accurate he has been the reader may also judge. When we consider that he does not dissent from nine of my statements and, furthermore, that he straightway gives another as his chief obection to my article, I think we can justly conclude that the headlines written by Dr. Blue were incorrect if not misleading.

Dr. Blue writes: "The chief objection raised is the coupling of the refusal of the U. S. Public Health Service to license lipovaccines with the statements which imply that for this reason people are being deprived of a valuable prophylactic agent." He justified the action of the service by the statement: "The lack at present of satisfactory potency and sterility tests for lipovaccines had led the Bureau to decline to license such vaccines for interstate sale, and the evidence at our disposal indicates that a saline vaccine containing pneumococci is at least as effective as an oil suspension of the organism."

I say the Public Health Service has made it impossible for most of the people to get influenza-pneumonia vaccines and (human nature being as it is) practically speaking, to prevent influenza-pneumonia vaccination. Dr. Blue says that at least the first part of the statement is correct, the Public Health Service having gone to the limit of their powers to make lipovaccines unavailable. I say that people who can get lipovaccines are lucky. Dr. Blue denies this, and justifies the action of the Service on two grounds—lack of confidence in the sterility of influenza-pneumonia vaccines and lack of faith in their efficacy. Here, as Dr. Blue says, is the real point of controversy, the chief reason, for his open letter.

First, as to sterility. I assume that what Dr. Blue meant to say is that it is difficult to sterilize lipovaccines. Lipovaccines made according to the older method were in fairly wide use in the army last winter. I have not seen any reports of any great harm due to lack of sterility. However, a simpler method of manufacture has been in use for more than six months. It was described by Rosenow in June last and the description appeared in the *Journal of the American Medical Association* shortly thereafter. Using this method it is just as easy to make sterile lipovaccine as to make sterile saline vaccine and far easier than to make sterile smallpox vaccine—a product licensed by the U. S. Public Health Service.

Second, as to potency. I am not certain what potency tests Dr. Blue refers to. He may refer to lack of laboratory demonstration by the McCoy test or to lack of clinical proof of potency. This objection to influenza-pneumonia vaccines was raised frequently in October, 1918. Without going deeply into it it seems to me that so far as the pneumococcus is concerned the evidence is very good that it can be used, in the laboratory, to produce specific antibodies, and, clinically, to produce immunity as to streptococcus. The evidence is fairly good that it produces specific antibodies in laboratory animals. There is lack of agreement as to the degree of effectiveness in antibody formation with lipovaccines as compared with saline vaccines.

As I understand it, the position taken by Dr. Blue is that if the Service were to permit the manufacture of lipovaccines they would be in the position of guaranteeing their efficacy to an extent. This he declines to do. May I ask him, "Does the Public Health Service guarantee the efficacy of saline vaccines against influenza?"

I have before me catalogues of biological products used for colds and a variety of disorders put out under license of the U. S. Public Health Service. Does the Service guarantee the efficacy of each of these? Or do they stand behind them in the sense in which they decline to stand behind lipovaccines? The last half of the sentence quoted is: "The evidence at our disposal indicating that a saline vaccine containing pneumococci is at least as effective as an oil suspension of the organism." Suppose we ask, on the basis of this statement, why license the one and refuse to license the other?

The point made in favor of lipovaccines in my article was that using lipovaccines, vaccination can be done at one sitting, whereas three sittings extending over three weeks are required for vaccination when done with saline vaccines. Vaccination at three sittings is possible in military life. In civil life it does not work. In ordinary times for the civilian life, for the uses of municipal and State health departments, the only vaccination worth talking about is one-sitting vaccination.

Now, Dr. Blue may be right as to a laboratory proposition that a saline vaccine containing pneumococci is at least as effective as an oil suspension of the organism, but when it comes to fighting pneumonia and influenza among civilians he is just about as wrong as a man could be. His action is equivalent to saying influenza-pneumonia vaccination shall not be done generally. I do not think this a wise decision.

W. A. Evans, M.D.

Chicago, November 14.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, October 31, 1919.

The Harveian Lecture at the Medical Society of London.—On Oct. 24, at the rooms of the Medical Society of London, Sir Berkeley Moynihan gave the opening Harveian lecture on gastric ulcer. The lec-

ture was a remarkably clear exposition of the surgeon's well-known views on the subject, many of which are original and by no means in agreement with those held by perhaps the majority of surgeons. In fact, he stated plainly that there must be a ruthless revision of present-day views so far as gastric ulcer was concerned. He began by explaining the situation of gastric ulcer, or rather by demonstrating how to differentiate between gastric and duodenal ulcer. It was pointed out that the pyloric vein was a sufficiently accurate landmark of the position of the pyloric, showing which was duodenum and which stomach. The features which differentiated gastric from duodenal ulcer were that carcinoma occurs on the base of a gastric ulcer, but seldom in duodenal ulcer; gastric ulcer is somewhat rare and extremely difficult to diagnose correctly; duodenal ulcer is more common and easier of diagnosis; pain in gastric ulcer is regular and occurs fairly early after food; in duodenal ulcer, in the majority of cases, pain occurs two hours or more after meals; in gastric ulcer relief of pain occurs before the next meal is taken; in duodenal ulcer pain is constant; the pain appears earlier in gastric ulcer and is worse when the ulcer is near the cardia than when it is in the body of the stomach; pain in the back is very severe when a gastric ulcer erodes the peritoneum. Lassitude before pain sets in may be due to intestinal toxemia. Regularity of pain is a main feature of gastric ulcer and it occurs twice more frequently in men than in women, judging from statistics of operations. Vomiting is infrequent in gastric ulcer, nor is hematemesis common. In 25 per cent of the cases in which Moynihan operated hematemesis occurred, and in these there was an element of doubt. Of all the methods of diagnosing gastric ulcer Moynihan awards the palm to the *x*-ray. Indeed, he estimates the value of the *x*-ray as a means of diagnosis as equal to that of all the other methods put together. Hyperchlorhydria, he said, was a capricious symptom and one upon which no great reliance could be placed. The point was again emphasized that more mistakes are made in the diagnosis of gastric ulcer than in that of any other abdominal disease. According to Moynihan the only sure means of diagnosing gastric ulcer was by the *x*-ray or by incision through the abdominal wall. As for medical treatment, the speaker did not express himself too favorably. He stated that treatment for reduction of acidity was of little use in the treatment of gastric ulcer. He pointed out that when treatment by medical measures is successful, that is to say, when the ulcer heals, it is not permanent, or it leaves a scar, to remove which an operation has usually to be performed. Moynihan has given up gastroenterostomy for some time, mainly for the reason that in his opinion there is always the danger of carcinoma forming on the base of the ulcer. He, therefore, now invariably does a gastrectomy for gastric ulcer, thereby avoiding any risk of malignant disease occurring. He praised the operation of Balfour, of the Mayo Clinic, but prefers gastrectomy to any. Of course, every surgeon is not able to do a gastrectomy with confidence, but he holds that, undertaken by a man who thoroughly knows his work, it is in the long run the operation which insures the most permanently successful results.

Voluntary Aid Scheme for the Promotion of Public Health.—At the Tuberculosis Conference held recently in London, Sir Arthur Stanley, the head of the British Red Cross Society, outlined a plan by which the workers who had so willingly and in such large numbers offered their services and worked zealously throughout the war might continue these services to assist in the work of reconstruction. On Oct. 23, in order to further consider the scheme drafted by the joint committee of the British Red Cross Society and the Order of St. John, a conference was held in the picture gallery of St. James Palace. Sir Arthur Stanley presided and pointed out that the primary object of the gathering was to consider the future constitution of the Voluntary Aid Detachments in their association with the British Red Cross and the Order of St. John. During the war there was a great need for voluntary aid and an eager readiness to render it. But reorganization for the time of peace had now to be considered, and if the War Office, under which they had worked before, had less need of them, there were the two new Ministries of Pensions and Health which had come into existence. Dr. Addison, the Minister of Health, said there was no end to the opportunities for well-considered work among the British population, and the fact that the Voluntary Aid Detachment was prepared to enter the field would do much to promote unity of action and secure a practical policy avoiding duplication of well-meant efforts. On what might be termed the domestic side he urged that the opportunities were wide as humanity itself. Through the nurses there would be the spread of knowledge which would do much to improve the daily methods and habits of life, and of the control of the homes of the people.

Influenza in Great Britain.—The Ministry of Health announced a short time ago that during the past few weeks there had been in the ninety-six great towns of England and Wales a slight but gradual increase in the number of deaths attributed to influenza, and a coincident rise in the number of notifications of acute primary and acute influenzal pneumonia. The increase appeared to have been associated with prevailing meteorological conditions and did not apparently signify more than the usual variation in catarrhal and lung diseases generally, which might be expected at this season of the year. While the possibility of a fresh outbreak cannot be excluded, the data available did not at present afford any indication of an immediate recrudescence of the disease in epidemic form.

Opening of the Winter Session at the Scotch Universities.—Like the English, the Scotch Universities are overcrowded. But whereas in England the medical students at the universities are in a minority, they constitute the greater proportion of students by far in the Scotch universities, with the exception of St. Andrews. On October 17, Professor E. D. Boyd, of the University of Edinburgh, delivered his inaugural address, discussing clinical medicine in Edinburgh in the past and present. He pointed out that teaching of clinical medicine in Edinburgh was bound up with that of the Royal Infirmary and the Royal College of Physicians. A charter was obtained for the college in 1681. George Drummond, the then chief magistrate of Edin-

burgh, had a great deal to do with the founding of the Royal Infirmary. A royal charter was obtained in 1736 and plans drawn up for a hospital to accommodate 226 patients. A great deal was owed to John Hughes Bennet, professor of medicine and clinical medicine from 1848 to 1874. He was, in fact, the founder of the present methods of teaching. But the erection of the present Royal Infirmary greatly aided in making Edinburgh the great medical teaching center it now is. Professor Boyd laid special stress on the importance of bedside work. It was in the wards that practical physcians were made and not in the lecture rooms.

The Harvenian Oration at the Royal College of Physicians.—On the afternoon of October 18, the Harveian oration was delivered by Dr. Raymond Crawford at the house of the Royal College of Physicians of London. The Royal College of Physicians of London is probably the most ancient medical society in Europe. It was founded in 1518 in the reign of Henry VIII. Its foundation was chiefly due to Dr. Thomas Linacre. The building of the Royal College of Physicians is in keeping with the honored traditions and with the dignity and attainments of its members. It is a stately, almost magnificent building, designed and erected at a time when spaciousness and art were more greatly esteemed features of architecture than at the present time. Its rooms and halls are large, lofty and well proportioned and the walls are adorned by numerous paintings, the majority of which are portraits of British physicians, many of whom lived years ago. For example, in the library in which the oration is given, the celebrated Dr. Radcliffe looks down from the walls wearing the full bottomed wig and the dress of the physician of the period, not forgetting that he bears in his hand the gold headed cane, symbol of his profession. Some of the paintings are by celebrated artists and are of very considerable value. The oration is delivered with a good deal of ceremony. The scene is impressive, almost picturesque. The wainscoted library, with its shelves of somberly but luxuriously bound books, the handsome and massive furniture, the coal fire brightly burning in open grates, and the scarlet gowns of the fellows of the college, make up a striking picture. As the address is about to be given the President of the College, vested in a black damask gown embroidered with gold, preceded by the white haired mace bearer, and carrying in his hand a silver sceptre or rod of office, goes to the chair. After him the Fellows and the orator of the day troop in. The mace is placed on the table in front of the President. It may be said that the scepter, which has four small serpents at the top, was made in 1556, and was first borne by Dr. Caius, the President, after whom Caius College, Cambridge, is named. It is interesting to note that the desk at which the orator stands is lighted by wax candles placed in old fashioned silver candlesticks. Dr. Raymond Crawford, who delivered the oration this year to keep green the memory of Harvey, spoke on the anatomical and physiological knowledge of those great Greeks, Aristotle, Erasistratus and Galen, and pointed out that Harvey derived his inspiration rather from these men than from the anatomists and physiologists of the Renaissance. Dr. Crawford seemed to wish to convey the impression that these latter have been overestimated and drew attention to certain points possessed in common by the father of anatomy, Aristotle, and the discoverer of the circulation of the blood. Both had Kings as patients. The Greek, the Macedonian King, father of Philip of Macedon. The Englishman, the ill starred Charles Stuart, but to whom Dr. Crawford thinks great honor is due for his generous and intelligent recognition of Harvey. Aristotle's investigations into the manner in which the heart performed its functions was greatly handicapped by the fact that he could experiment only upon animals owing to the religious prejudices of the Greeks. After all, Harvey's discovery was but a modification, although an essential one, of Aristotle's findings. Aristotle, however, like Erasistratus and Galen, failed to grasp the essential conception that blood travels in a circle. Erasistratus, a member of the celebrated Alexandrian School, carried Aristotle's belief somewhat further, while Galen went still further, blending the conception of the two former pioneers. Aristotle was a marvellous anatomist and almost the father of physiology. The object of Dr. Crawford's oration was to show the debt that Harvey owed and acknowledged to these old masters and to Aristotle in particular. After the close of the oration Dr. Norman Moore, the President, presented the Bailey medal for scientific research to Dr. Leonard Hill.

Appointments.—Colonel J. G. Adami, formerly Professor of Pathology at McGill University, Montreal, has been appointed Chancellor of Liverpool University. Lieut.-Col. J. C. Meakins, Lecturer in Clinical Medicine at McGill University, Montreal, has accepted an important post at Edinburgh University.

Obituary.—Dr. Arthur Neve, whose work with regard to plague is well known to the American medical profession, died suddenly on Sept. 5, at the C. M. S. Hospital in Kashmir, of which he was chief. Dr. Neve qualified from Edinburgh University in 1880 and four years later became F. R. C. S., Edinburgh. He entered the service of the British Church Missionary Society and was sent to Kashmir, where he spent practically the working years of his life. His brother, Ernest, joined him and these brothers made of the Kashmir Hospital a model for all the hospitals of India. Dr. Neve returned to England in the early part of the war and being given a temporary commission as major in the R. A. M. C., served first at the hospital for Indian soldiers in Brighton and later as surgical divisional officer in the war hospital at Dartford. He had returned to Kashmir only six months before his death.

1. Potential and Acquired Static Flat Foot.—Edward H. Ochsner defines potential flat foot as a weakened condition of the arch due to a disproportion existing between the strength of the foot and the strain to which it is exposed, in which the strain has not been severe enough to break the arch. Acquired static flat foot is described as an acquired compound deformity in which the foot assumes an abnormal relation to the leg and the bones of the foot abnormal relations to each other. This results in improper distribution of weight and strain, abnormal function and loss of arch. In order that treatment may be uniformly successful in both types of cases it is absolutely essential that the physician in charge of the case keep constantly in mind certain fundamental facts in reference to the anatomy, pathology, etiology, and symptomatology of this condition. The normal shape of the foot is maintained by three distinct factors: First, the shape of the bones; second, the ligaments and fascia, and finally, the muscles. If a disproportion exists between the weight which is borne and the strength of all of these three factors, the longitudinal arch must give and flat foot results. The first to suffer in the development of flat foot are usually the muscles. The ligaments and fascia come next and deformity of the bones last. General muscular weakness predisposes to flat foot, but the tibialis anticus and the tibialis posticus are the two muscles most involved in this condition. If they become weakened or overstretched, the foot is abducted and averted, the weight of the body is then borne not on the centre of the arch but internally to it and the arch is put to a very great mechanical disadvantage, with the result that in extreme cases the relation of the trasal bones to each other is markedly changed and ultimately even their shape becomes altered. The etiology of this condition may be divided into three main classes: First, relative weakness of the muscles; second, excessive weight bearing; third, anything which has a tendency to disturb the proper relation of the bones to each other, such as faulty attitudes and faulty footwear. Among the most common causes which produce weakness of the muscles the writer mentions acute and chronic diseases and puberty. In the discussion of faulty footwear he deprecates the use of arch supporters, whether sold by the shoe merchant or prescribed by the orthopedist. Some of the first symptoms to be complained of by the patient in the development of flat foot are cyanosis, coldness, numbness, sweating of the feet, fatigue on the slightest exertion, and general ill-defined discomfort. The first and never failing sign is an outward deflection of the tendon Achillis. Another early sign is the tendency to assume the attitude of rest, unconsciously, in the hope of relieving the tired muscles and throwing the strain upon the bones and ligaments. The more often it is assumed the more pronounced the peculiar abduction will become. Eversion of the foot and the ultimate breaking of the arch follow. There is no direct relationship between the sinking of the arch and the severity of the symptoms or the degree of disability. A beginning flat foot may be so painful as to utterly incapaciate the patient from all work and yet show no loss of arch. The abnormal relation of the foot and leg in the compound deformity which constitutes flat foot causes an improper distribution of weight and strain and disuse of normal function which is of far greater importance than the depression of the arch. If the factors producing the tendency of flat foot are not relieved the fatigue and discomfort will become actual pain, which can usually be analyzed as occurring in one or more of the following seven points: 1. Where the tuberosity of the scaphoid and the head of the astragalus make prssure on the calcaneoscaphoid ligament. 2. Middorsum of the foot where scaphoid impinges on the neck of the astragalus. 3. On the outer surface of the foot, which, because of the rotation, the external malleolus rubs against the astragalus. 4. Plantar surface of heel. 5. At metatarsophalangeal junction. 6. Pain in thighs, hips, and back. 7. Calf pains due to spasm of calf muscles. These pains, as well as the changed relations of the bones of the lower extremity, result in the peculiar gait of the flat foot patient. The treatment is both prophylactic and curative. In order to prevent the development of flat foot, the general hygiene must be looked after. This includes the provision of alternate periods of rest and exercise, the avoidance of excessive strain, the correction of obesity when it exists, the development of proper standing and walking, the use of proper shoes and stockings, and, as previously suggested, the taboo of arch supporters. When flat foot has actually developed these prophylactic measures must be supplemented by other remedies, one of the most important of which is suitable physical exercises which will improve the general muscular development and especially the development of the tibialis anticus and the posticus muscles. Special attention is directed to the writer's method of strapping, the directions for which have the one object of using adhesive plaster to the greatest advantage. Zinc oxide adhesive plaster in twelve inch rolls is used. The patient's leg is measured and the adhesive straps marked off according to the length of the extremity. For the purpose of strapping an adult male patient's foot of ordinary size he marks off seven strips half an inch wide by thirty-two inches long, with a cross line at the middle, fourteen strips half an inch wide by eight inches long, one strip half an inch wide by sixteen inches long. The heel of the patient's disrobed foot is placed on a chair, the knee flexed and with a short hard roller bandage looped around the foot the patient is directed to draw the toes upward, thus placing the foot at a little less than a right angle to the leg, at the same time having it moderately inverted and adducted. The middle of a thirty-two by a half inch strap is now placed over the bottom of the heel about an inch from its posterior border, half of it placed up the outer surface of the leg without tension and the other half up the inner surface of the leg, applying this as taut as possible. One of the short, narrow strips is then placed on the inner surface of the foot parallel with the sole and one on the outer surface. The remaining long and short straps are now applied alternately in the same manner, each one slightly overlapping its predecessor. When these are all in place they are covered with transverse straps three and one quarter inches wide, beginning at the top and overlapping about a quarter. He is careful not to allow these transverse straps to meet posteriorly. These straps will remain in place and be effective for from four to eight weeks, when they may be removed in the evening with benzine or with cold cream, the foot washed with soap and warm water, carefully dried, and restrapped the next morning. This can be repeated until a cure is obtained, which may require from two to ten strappings. The relief is almost immediate.

2. A Clinical Study on the Use of Calomel Inunctions.—H. N. Cole and Sidney Littman describe their observations on a series of 54 patients treated intensively with calomel rubs. They found that in these patients calomel inunctions were almost totally inefficient against primary and secondary syphilis, and that calomel inunctions rarely produce salivation or gingivities. This means poor absorption of the mer-

cury and explains the clinical inefficiency of this method of administering calomel. Calomel rubs, they find, may occasionally produce a dermatitis. These results have led them to abandon calomel inunctions and they strongly advise against their further use in the treatment of syphilis.

4. Factors Influencing Recovery and Resolution in Lobar Pneumonia, with Special Reference to the Pneumonic Exudate.—Frederick T. Lord. (See MEDICAL RECORD, xcvi, No. 11, pp. 480.)

9. The Fundamental Physiologic Reaction in Anaphylactic and Peptone Shock.—J. P. Simonds presents this preliminary report in which he calls attention to the remarkable difference in the manifestations of anaphylactic and peptone shock in different animals. In the dog, anaphylactic and peptone shock are characterized by a marked and immediate fall in arterial blood pressure, a simultaneous fall in venous pressure, a rise in portal pressure, an increase in the volume in the liver, and, at least in peptone shock, an increased flow of lymph from the thoracic duct. It is evident, therefore, that in the dog, the flow of blood through the liver is greatly impeded in these conditions. The exact location of the obstruction has not heretofore been determined. Reasoning from these facts it appears that the only possible location for an obstruction that would explain all of them is not the extrahepatic splanchnic area, nor the portal vein and its intrahepatic branches, nor the intralobular capillaries, but the hepatic vein and its branches. It has been shown that a fall in blood pressure such as is seen in the dog and is not characteristic of anaphylactic shock in the guinea-pig or in the rabbit, or in peptone shock in the guinea-pig. In searching for the reason for this difference, the writer has made a study of the comparative anatomy of the hepatic vein in different animals. It has been found that the hepatic vein in dogs differs from that of the guinea-pig, rabbit, and other herbiverous animals examined, in the relatively enormous amount of smooth muscle which it presents in its walls. It appears, therefore, that the fundamental physiological reaction in anaphylactic and peptone shock in dogs is a spasm of the smooth muscle in the walls of the hepatic vein and its branches. This interpretation of the physiological mechanism of anaphylactic and peptone shock has certain practical bearings. If the basis for these differences in the reaction of different animals in shock of this kind is an anatomical difference in the distribution of smooth muscle in the body, a similar anatomical anomaly may also account for certain types of asthma and serum reactions in human beings. This observation may also bring peptome shock into relation with surgical and wound shock. In this connection it is only necessary to recall that among the theories advanced by various authors who have studied shock under war conditions is one that makes the absorption of the soluble products of damaged muscle in wounds responsible for the condition. It is evident, also, that in interpreting the results of experiments on dogs, especially those which have to do with blood pressure, this peculiarity of the hepatic vein must be taken into consideration.

10. The Metabolic Gradient Underlying Peristalsis.—Walter C. Alvarez states that during the past two years he has been able to show that there is a definite gradient of oxidation and carbon dioxide production in the intestinal wall, underlying and probably giving rise to the other gradients of rhythmicity, tone, etc. In other words, the chemical processes of life go on at a faster rate in the duodenum than in the ileum or colon. Theoretically if we should speed up these processes in the duodenum we might steepen the gradient and cause the food to go faster through the bowel; if we should speed them up in the ileum so that they would be faster than those in the duodenum, we might reverse the gradient and stop the downward progress of food. Recent study has shown that the local life processes are speeded up by inflammation so it may be that the hypermotility actually seen in many cases of duodenal ulcer and cholecystitis and the hypermotility with appendicitis are due to changes in the metabolic gradient brought about by these lesions. Galvanometric studies of bruised tissues suggest strongly that their metabolic rates are increased by the trauma. Since the heart beat follows a gradient of rhythmicity and almost undoubtedly one of metabolism, it would be expected that certain drugs and disease toxins would reverse it as they reverse other metabolic gradients. A review of the literature shows considerable evidence in favor of such a view. Thus chloroform will paralyze the auricle in concentrations which will only slightly inhibit the ventricle; digitalis has a similar tendency, and we must begin to ask ourselves whether this action may not flatten or reverse the gradient. Such changes might account for some of the retarding in conduction and also for the tendency to heart block and a reversal of the beat. Similar upsets, with palpitation, nodal rhythm, and even transitory blocks, may arise through the activity of disease toxins. The disordered heart action and the digestive disturbances seen side by side in people recovering from infections such as influenza may easily be due to the flattening effect of the one poison on the two gradients. The writer feels hopeful that further study of the digestive gradients and of their modification in disease will not only bring rich rewards to those interested in gastroenterology, but will also enable them to repay the heart physiologists and biologists with interest for the loans of their methods and working hypotheses.

3. Two Studies of Meningococcus Carriers.—1. The Site of Carrying in Chronic Meningococcus Carriers.—Denis Embleton and W. Sohier Bryant report on investigations made on 40 chronic carriers, 21 of whom had already suffered from cerebrospinal fever, and 19 had never had the disease, but were found to be carriers on examination of the nasopharynx. The sites from which cultures were taken were, through the nose, the anterior ends of the lower turbinates, anterior ends of the middle turbinates, posterior ends of the lower turbinates, anterior wall of the sphenoid, fossæ of Rosenmüller (upper), and Luschka's tonsil; through the mouth, faucial tonsil crypts, fossæ of Rosenmüller (lower) and back wall of the nasopharynx. The technique is described and the results in each of these localities tabulated. From these results the writers conclude that the sites of carrying in the chronic meningococcus carrier are Luschka's tonsil, the fossæ of Rosenmüller, the posterior nasopharyngeal wall, and the faucial tonsils. The anterior and upper parts of the nose are not, as a rule, infected. The presence of lymphoid hypertrophy and nasal obstruction, although it may favor the production of a chronic carrier, is not of necessity the cause. It appears that the meningococcus disappears from the nasopharynx when an invasion of some other bacterium is successful. The factor which was by far the most powerful in eliminating the meningococcus in the chronic carrier was the "incidence of a cold in the head." The chronic carrier, however, seemed to be relatively immune to "colds."

II. Meningococcus Carriers.—Dennis Embleton and George H. Steven investigated 905 carriers at the Netley Cerebrospinal Fever Center, between September 29, 1916, and April 26, 1919. They discuss the subject in cases and contacts of cerebrospinal fever under the heads: (1) Acute and Chronic Carriers. (2) Treatment of Carriers. (3) Mechanism of Elimination of the Meningococcus. (4) Nonagglutinable (?) Meningococcus Colonies. (5) Bacterial Replacement of the Meningococcus. From this study they conclude as follows: (1) Meningococcus carriers can be divided

into two groups: (*a*) Acute or temporary carriers, those carrying under eight weeks; (*b*) chronic carriers, those carrying over eight weeks. (2) Acute or temporary carriers remain infectious on an average of twenty-four days; the maximum discharge rate occurs the third week. (3) Chronic carriers remain infectious on an average for five and one-half months; the longest carrying period found was 634 days, or one year and nine months. (4) Eighty per cent. of carriers are acute or temporary, 20 per cent. chronic. (5) The type of coccus carried rarely changes; in 905 carriers this was only observed to occur once. (6) Treatment of the carrier appears to prolong the carrier period. (7) The meningococcus remains in the "carrying site" until ousted by some other bacterium. (8) A large number of nonagglutinable organisms, otherwise indistinguishable from the meningococcus, are probably altered meningococci. (9) The best method of freeing a meningococcus carrier from infection is Nature, open air, and exercise. If the idea is accepted that the meningococcus disappears from the carrying site when ousted by some other bacterium, it does not seem to the writers that surgical interference is indicated, because there is probably a certain degree of risk of provoking cerebrospinal fever by surgical manipulation of the meningococcus carrying site, and because if the meningococcus can invade hypertrophied lymphoid tissue, so with equal ease can organisms replace it.

5. The Balance of Colloid and Crystalloid in Cholera, Shock, and Allied Condition.—Benjamin Moore refers to two articles published in the *Journal* of September 20, 1919, pp. 387, 394, one from France and the other from India, which spread much light upon each other and upon several outstanding obscure facts in the study of immunity. The first is a review of recent work Richet, Brodin and Sait-Girons in anaphylactic shock, in which it is shown that such shock can be prevented by addition of sodium chloride to the dechaining dose of serum, or by rendering the blood hypertonic with saline before this serum is injected. The second is a letter from Sir Leonard Rogers pointing out that while intravenous injections of hypertonic salines in cholera are of well proven advantage similar injections of gum arabic as used by Bayliss so effectually in combatting wound shock, or surgical shock, are here of no avail but rather appear to be a disadvantage. Moore finds these two sets of observations by no means contradictory but most beautifully complemental, and that both are in consonance with the findings of the French school on anaphylaxis and with the earlier observations from India of Sutherland and McCay that hypertonic salines inhibit hemolysis either in a natural hemolytic system or an actively created one with a specific hemolysin, as in the Bordet-Genou reaction and the Wassermann test. The common cause of all these phenomena is a disturbance of the delicate equilibrium between the colloids of the blood and cells (such as proteins and lipoids) and the crystalloids (such as sodium chloride) existing united or absorbed in common solution or suspension. Taking the positive effect of a colloid, such as blood proteins, gelatine, or gum acacia, in shock due to hemorrhage, surgical injury, or prolonged anesthesia, as compared with the failure of simple hypertonic salines under these conditions, it is found that the situation is one of a circulating fluid not merely refective in total volume but also relatively poor in colloid compared to crystalloid. Accordingly inorganic salts, or salines given alone, are here rapidly eliminated, having no colloid to anchor them, and so being treated as foreign bodies and thrown out of the kidneys and intestines. But gum arabic, gelatine, and plasma proteins cannot be so expelled and serve to anchor inorganic salts and so preserve the equilibrium of crystalloid and colloid not only in the blood but in the master cells of brain and heart, where the state of aggregation of the protoplasm would soon become altered. That there is such an interaction of adsorptive character between colloid and crystalloid is shown by the definite changes in osmotic pressure following upon variations in the concentration of the salines in which the colloid is in solution. Taking the efficiency of hypertonic salines in cholera, and inefficiency of colloidal solutions such as gums, it is clear that this is as it ought to be, for the condition is one of excess of toxic colloids and defect of balancing electrolytes or salines. The crystallo-colloidal balance in this case is upset in the opposite direction. Electrolytes are wanted to combine wtih circulating toxic colloids and with colloids of tissue to prevent these linking on to each other. Gum injections under such conditions only furnish another claimant on that side of the balance for the already denuded concentration of crystalloids to cope with. On the other hand, free saline in the blood in such diseases as cholera, combines with toxins to form a crystallo-colloidal union, and this is an essential factor in excretion of the poison by intestine and kidney. The unattached colloidal molecule possesses no osmotic pressure, nothing to drive it through an excreting cell. When it becomes attached to a crystalloid the combination acquires a directive force and the power of diffusion. An exactly similar explanation can be given for the results obtained in the prevention of anaphylactic shock by hypertonic saline, only here the colloidal constituent, or antigen, attacked, or protected is probably lipoidal in nature, as it is in syphilis and the Bordet-Genou phenomenon. The most striking instance of all this delicate equipoise between colloids and crystalloids is the regulation of the amount of saline in the cells and circulating fluids of the body. From the evolutionary point of view this regulation is much more ancient than that of body temperature, and its pathological variations are probably much more important than those of the temperature could we only discover as ready a means of studying them as is the clinical thermometer in the case of temperature.

Indianapolis Medical Journal.

1. Is Carbuncle a Medical or a Surgical Disease? Douglas H. Stewart.
2. Observations from Nine Months in Oto-Laryngology Base Hospital, Camp Taylor. John Carmack.
3. Radium in Dermatology. T. C. Kennedy and W. H. Kennedy.

3. Radium in Dermatology.—T. C. and W. H. KENNEDY state that the results from radium treatment have more than met their expectations in many skin lesions. However, it must not be considered a specific, but simply an auxiliary of great value. In their experience the following skin diseases have yielded to radium treatment: Lupus erythematosus, lupus vulgaris, keloids, krausosis vulvae, rodent ulcer, cancer of the skin, chronic eczema, "birth marks," puritis, angiomas, acne, rosacea, sycosis, rhynophyma. Two cases of lupus erythematosus which were very resistent, and in which carbon dioxide had been used without success, finally yielded to radium treatment. From 25 mgs. to 50 mgs. of radium was applied in these cases, this being a much larger dose than is ordinarily required in the treatment of lupus erythematosus. When keloid is of recent origin radium almost invariably effects an absorption of the scar tissue. In one case following an abdominal incision keloid tissue was found the full length of the incision and also at the site of each stitch hole. Following the application of radium pain and discoloration were relieved and the prominence levelled. At the end of three years there is no recurrence. In the skin lesions of babies and young children radium is invaluable on account of the ease of application, there being no pain accompanying the treatment. As yet no standard dose of radium has been established and it is the custom of radium workers to establish their own standard as acquired from experience. The indiscriminate use of this powerful therapeutic agent must be condemned, since with too large a dose or insufficient screening a

necrosis of the skin may be produced which may be slow in healing, causing quite a considerable amount of pain and leaving a cosmetic effect which is undesirable.

Intravenous Injections of Pancreatic Extract in Cancer of the Stomach.—LOEPER has in a measure revived the Beard trypsin treatment of cancer, basing this upon the positive finds of accredited clinicians like von Leyden, who in turn was guided by the laboratory results of Blumenthal and Bergell. He is fully aware of the negative results obtained by men of clinical eminence. In reviving the resource he prèfers the intravenous method and has limited it to cancer of the stomach, naturally a condition difficult to ameliorate. He began with a colloidal suspension of pancreatic extract in a strength of 1 to 1000, and a solution in sterile water of one per cent. strength. With experience based thereon he then sought a more satisfactory injection of five to ten per cent. of the aqueous solution of the extract. This was filtered through a Chamberland filter and resterilized. This gave a strong yet safe preparation for intravenous use. It was thrown into a vein in the arm in dose of 1 to 2 ccm. The injections were made daily or every other day until 25 to 35 injections had been given. There was no thermic reaction but a lowering of vascular tension which marks the activity of the preparation. An initial leucopenia is followed by a strong leucocytosis. The injections were at first used in a number of miscellaneous cancers with negative results. On the other hand there was a distinctly favorable action on cancer of the stomach. On account of the metatases in some cases and the damage done to the pylorus by retraction the results were not always in evidence but in two special cases vomiting ceased, the appetite returned and weight was taken on. In these cases the blood picture showed a corresponding change for the better. Whether this favorable action is exerted directly upon the growth may be doubted. Rather it would seem that the defensive forces in the blood and organism at large are increased and the pancreatine plays the part of an antigen.

Le Progrès Médical.

October 4, 1919.

Onirism.—Laignel-Lavastine reports three cases of what he terms onirism or dream status. He calls attention to the teaching of Laségue that delirium tremens is not a true delirium but a dream state, and finds this explanation to hold good for conditions due to psychic trauma, not only in frank hystericals but apparently in non-hystericals. The first case was in a young woman who for 6 months had nursed her sick employer who finally sucumbed. Grieved and exhausted, she was still obliged to watch the corpse at night. Suddenly the dead appeared to her to speak saying that he was still alive and asking for a drink. She experienced a fright but attended the funeral. After this she remembered nothing until she found herself in the hospital. She had been admitted for confusional state of typical character with disorientation as to time and place. She was agitated and trembling, wept, had visual and auditory hallucinations. She saw her late employer ill and heard him ask for water and to get up. The condition lasted for 3 days and was followed by sense of fatigue and lacunar amnesia. The condition is a very simple one—the psychic shock of the death plunged the subject into a dream state. Such episodes were very common durin the war. As she recovered her mental equilibrium she was left with a headache which slowly wore off. Another case occurred in a woman notably hysterical who found her husband dead from suicide. She neither ate nor slept as a result of the shock, and began to suffer from dream hallucinations. There was no confusion as in the first case, but after recovery she continued to believe in the reality of some of her hallucinations. A third case in an old woman with belief in her mission of evangelization of soldiers showed systematized delusions and exaggerated ego. The case would ordinarily have passed as a true psychosis, but a close study showed that the hallucinations were essentially hypnagogic. However, the subject was doubtless a hypomanic and only the hallucinations, which as a rule are absent in mania, were motivated by sleep.

Correspondenz-Blatt für Schweizer Aerzte.

August 28, 1919.

Action of Tuberculosis on the Psyche and Character.—Amrein devotes a long study to this subject without reference to the large literature. As a sanitarium phthisiologist he is evidently guided by his own finds but his paper is written with some reference to one on the same subject by Romisch in 1904. The psyche in this connection implies the inner existence and the character the outward expression. Naturally the specialist in a long career sees all kinds from irresponsibles to heroes. The psyche and character of the child victim may be omitted in this connection although when the adult consumptive has suffered in childhood, tuberculosis as well, the early experiences must powerfully affect the mind in one way or another. Most consumptives are young adults or old adolescents whose characters have not had time for development. Other writers on the subject seem to have assumed tacitly that the victim has reached sufficiently mature years to show some responsibility. In such a case there must be a great conflict between the inclinations and the fate which seems to impend. The beneficent effects of work upon the character may not be realized if the subject is an invalid and under strict treatment. The victims are often young people of unusual talent and promise who are ambitious for themselves or others. Incapacitated for work they must think and speculate. They become introspective and upon the one subject of their disease. They read popular articles about consumption and how to avoid and cure it. A singular fact even on the part of the scholarly is a form of the deterioration of taste. While at first one notes the taste for the classics these are in time replaced by stories of crime and its detection. The decline does not stop here for the next step is to read the frivolous and then to be indifferent to all literature. Even the newspapers pall. In other words the patient suffers from a progressive secondary neurasthenia which goes far to explain his mental make-up. He may even be classed as psychasthenic with his obsessions of using the thermometer at all times and much behavior of the same type. If fairly able to get about he indulges in alcohol and flirtations and his motto seems to be *cape diem*. Idleness is largely responsible for all moral delinquencies, plus the tendency to make the most of what remains of life. His behavior is not paradoxical but about what it would be under his peculiar circumstances.

Nitrous Oxide-Oxygen Anesthesia in France.—For some not stated reason the French surgeon has remained indifferent to this form of surgical narcosis despite the free use of the same in England and the United States. Desmarest and Amiot, however, have devised a convenient apparatus for administering the combination and it is hoped that the latter will soon receive a thorough tryout.—*La Presse Médicale*

The Occurrence of Clubbed Fingers in Healthy Persons as a Familial Peculiarity.—Dr. F. Parkes Weber observes that clubbing of the fingers is so well known as an acquired pathological condition, especially in connection with disease of the thoracic viscera, that its occasional occurrence in healthy persons as a familial (and doubtless also congenital) peculiarity deserves some attention. He reports cases of twin brothers, 25 years of age, both of whom show clubbing of the fingers of both hands. In one of these brothers the thorax was not well developed, but the clubbing was not as marked in this man as in his rather better developed brother. These men were both regarded as suitable for life insurance at ordinary rates. Neither the father nor the mother showed evidence of this peculiarity. He reports another case in which the clubbing of the fingers seemed to be inherited, though it was not associated with any thoracic or other disease, and reviews several recorded cases of a similar peculiarity.—*British Medical Journal*

Book Reviews.

THE ITINERARY OF A BREAKFAST. A Popular Account of the Travels of a Breakfast Through the Food Tubes and of the Ten Gates and Several Stations Through Which It Passes, also of the Obstacles Which It Sometimes Meets. By J. H. KELLOGG, M.D., Medical Director of the Battle Creek Sanitarium. New York and London: Funk and Wagnalls Company, 1919.

THE author of this little book needs no introduction to the medical public, for few are the doctors in this land who have not heard, whether or not they have heeded, his solemn warnings anent the indulgence in the flesh pots of Egypt. The land of Israel flowing with milk and honey is for him the symbol of the dietary of mankind. That he is an extremist in his views of hygienic eating, probably he himself would not deny, yet that many of his views, in particular his opposition to an excess of protein, especially animal protein, in the diet are in the main sound will be conceded by most practitioners today. There is a limit, however, to the possibility of acquiescence, and we fear Dr. Kellogg has passed beyond that limit when he insists upon the necessity of evacuating the colon at least three times a day, or after each meal. This is surely the opposite pole to the doctrine which was preached at one time of the sufficiency of one evacuation a week. Fortunately the reader of this really interesting little book is under no obligation to obey the author's injunction and there is very much else in the work that is well worth while regarding the process of digestion, the intestinal flora, and diet. A chapter which will afford interesting reading and one which will no doubt increase the author's reputation as an extremist is that on "Nuts a Coming Food Staple," the conclusion of which is that "nuts may save the race."

O INSTITUTO CRUZ, RESUMO HISTORICO, (1899-1918). Pelo Dr. EZEQUIEL DIAS, Director do Filial em Bello Houzonte. Rio de Janeiro: Manguinhos, 1918.

THIS establishment which corresponds to the Pasteur Institute of France and Rockefeller Institute of the United States, contains a research and teaching faculty of thirty-five men under Director Chagas. There are four chiefs of services and seventeen assistants. The other members are in charge of special functions, such as librarian, photographer, secretarial work, typography and other bureaucratic activities. The number of those who have attended the courses was in 1918 twenty-eight, and the total number since the courses began is 143. Among them we recognize the names of many well-known Brazilian scientists active in various cities of the republic. Judging from the photographs and text, the plant is ample for every purpose, including all forms of hospital activities.

THE NERVOUS HEART. Its Nature, Causation, Prognosis, and Treatment. By R. M. WILSON, Captain, R.A.M.C., late Assistant to Sir James Mackenzie, under the Medical Research Committee; Cardiologist to the Trench Fever Research; Author of "The Hearts of Man," and JOHN H. CARROLL, Major, M.C., U.S.A. Specially Attached Trench Fever Committee; Assistant Visiting Physician, City Hospital, New York; Instructor in Clinical Medicine, University and Bellevue Hospital Medical College. New York: The Oxford University Press, American Branch, 1919.

IN this very readable little book the authors treat of the various forms under which functional disturbances of the heart manifest themselves. The subject is approached from the side of the nervous system rather than that of the myocardium. They do not oppose the belief that inefficiency of the myocardium must enter as a factor in cases of heart failure, so-called, but they insist upon the additional disadvantage under which the heart must act when there is a disturbance of its nervous control as well. The authors' argument can be better followed by one who has already read Wilson's interesting study of the physics of the circulation contained in his work in "The Hearts of Man," for while this is not a sequel of that work, the authors nevertheless refer to it frequently in the course of their argument. The reviewer, while recommending the book as interesting and suggestive, would warn against the easy-going advice in the section on treatment. The writers state that they do not forbid their patients to smoke or drink alcohol and they pay no attention to diet. A practitioner who has seen a rise of pulse from 74 to 110 combined with intermittance, following the smoking of two or three pipes or cigarettes or who has seen an attack of angina or pseudo-angina occur every time the patient smokes a black cigar, could hardly in conscience tell the patient to go on accelerating and disordering his heart action by continued indulgence in tobacco, and the evil effects of large protein consumption in certain cases are too evident in certain instances to justify the physician in ignoring the question of diet.

THE MEDICAL RECORD VISITING LIST OR PHYSICIANS' DIARY for 1920. Revised. New York: William Wood and Company.

THIS well-known Visiting List contains a calendar for the period from July, 1919, to June, 1921, and the usual blanks for patients, consultation practice, obstetric engagements and practice, vaccinations, deaths, addresses of patients and of nurses, and cash account. There is also an assortment of miscellaneous information. This Visiting List has long enjoyed much popularity, it is well printed on good paper, is of convenient size, and presents a neat and attractive appearance.

PLASTIC SURGERY OF THE FACE, HEAD AND NECK. A Series of 90 Stereoscopic Illustrations Showing the Technic of Operations with a Text Volume of 132 Pages, Setting Forth the Principles of Plastic Surgery of the Face, Head and Neck, with Complete Case Reports, Thoroughly Illustrated. By JOSEPH C. BECK, M.D., F.A.C.S., and IRA FRANK, M.D., F.A.C.S. St. Louis: C. V. Mosby Co., 1919.

THE thick cardboard illustrations are detached and are packed in a suitable cardboard box with the text-manual; the whole presenting a very attractive and novel appearance, although the idea is by no means new. In addition to the legends beneath the illustrations the reverse of the individual cards gives further information. There is of course no stereoscope to accompany the cards, but presumably they may be used with a standard make. The text-manual gives 47 pages of operative technic and is also well illustrated in miniature with 33 plates, comprising many individual photographs.

THE HIGHER ASPECT OF NURSING. By GERTRUDE HARDING. Philadelphia and London: W. B. Saunders Company, 1919.

THE author feels that a manifold personal experience in nursing has qualified her not only to realize the existence of certain practical problems, but to solve them in part. Among the 27 chapters of the book some deal with trite themes while others appear decidedly novel. Thus the physician has it in his power to demoralize the nurse, and this result has often been brought about in several ways. The chapter on Discordant Magnetism seems fanciful, although not so much in the basic conceptions as in the terminology employed. With a few exceptions like the preceding, the chapters cover rules of conduct which apply to all callings of personal service and not only to nursing. Their application to the latter is often illustrated by examples in point. The book is a very readable one for the general public as well as the nurse and physician.

INDUSTRIAL NURSING FOR INDUSTRIAL, PUBLIC HEALTH AND PUPIL NURSES, AND FOR EMPLOYERS OF LABOR. By FLORENCE SWIFT WRIGHT, R. N. Bureau of Child Hygiene, New Jersey State Department of Health, etc., etc. New York: The Macmillan Company, 1919.

THIS volume, as the title implies, is devoted entirely to industrial nursing, and the 15 chapters cover the industrial nurse and her co-workers, first aid and visiting nursing, record keeping, the nursing center, the question of food, etc., etc. Industrial nursing deals with both accident and sickness and is said to be in its formative period. As far as can be seen, the industrial nurse functions for corporations engaged in manufacturing, who employ her often through employment agencies. The parent activity of nursing the employee gives use to others, such as supervision of his family, with reference especially to dietetics.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Thirty-Second Annual Meeting, Held at Cincinnati, Ohio, September 15, 16, and 17, 1919.

THE PRESIDENT, DR. JOHN F. ERDMANN OF NEW YORK CITY, IN THE CHAIR.

Symposium on Venereal Disease: The Work of the Detention Home for Women in the Management of Venereal Disease.—DR. PALMER FINDLEY of Omaha, Nebraska, stated that in June, 1918, at Fort Omaha, measures were taken to protect the soldiers from venereal disease. There were 600 or 800 boys in the Fort at the time. After the detention home was established, so that infected girls and women could be properly treated and cared for, the percentage of venereal disease in the soldiers was greatly reduced, and a great deal of valuable work was done in this regard.

The Value of Detention as a Reconstruction Measure.—DR. C. C. PIERCE, Assistant Surgeon-General, United States Public Health Service, Washington, D. C., said that the two years of war had given us volumes of data proving conclusively that the prostitute or sex offender required individual, correctional care to overcome the handicaps of mental inferiority, physical defects, educational neglect, and hereditary and environmental influences. The detention home had a definite place in the reconstruction program, but it must be a detention home only in the sense that individuals were detained until such time as they could be returned to society equipped to take their places as respectable and respected citizens. The ideal location for a detention home was in the country. This gave opportunity for outdoor exercise and work which was of great rehabilitating value. There must be sufficient space in order that the mentally normal could be separated from the sub-normal, that the girls be separated from the women, because the problem of moral contagion was as great as that of physical contagion. Competent medical attendance was essential. Adequate hospital facilities for the care of the venereal and other infections was imperative. The atmosphere of the place should be as home-like as possible, the personnel selected from women who were specially qualified and trained and who had a sympathetic interest and a belief in the movement. Merely to use a detention home for the cure and treatment of venereal diseases was to promote a vicious cycle. Unless the individual detained was given a vocational training whereby a decent economic status could be maintained the detention home contributed to delinquency rather than corrected it. The responsibility of the detention home in the matter of correctional therapy extended beyond the walls of the detention home. This responsibility was met only when an efficient system or follow-up was established and maintained. The war time detention house was designed primarily to meet an emergency, to protect the fighting men from venereal infections. The peace-time detention house for such an institution must be carried over with the peace-time program; it must be designed to protect the working forces—posterity—from venereal infections. The peace-time detention home, however, must be designed along different lines. It must provide correctional facilities, as well as medical facilities.

Pioneering in Venereal Disease Control.—DR. A. J. MCLAUGHLIN of Sioux City, Iowa, stated that educational methods such as authentic literature, lectures, etc., were a good thing to bring about a demand in different communities for suppression of these diseases; but the carriers were not reached by this form of control. Law enforcement was the only method through which they could be reached, and if the law enforcement was strict enough, venereal disease could be wiped out. There was a certain class of people that you might call the venders of vice, or the people who were making their living by promoting vice, backed by quack physicians, and cure-alls, and political power that were fighting work along this line, because enlightening the ignorant of the dangers of infection, and the liability of infection drove trade away from the cribs, and vice dens. One of the very important movements that was going to cut down the infections of venereal disease was the stopping of the sale of liquor. Many infections were contracted while a person was under the influence of intoxicants. About 90 per cent. of infections were due to women, and 10 per cent. to men. Men took more precautions and were more particular about treatment and prophylaxis. Women were very negligent, and took treatment only for the relief of pain or under compulsion. One woman would infect ten men for every one woman that one man would infect. Prophylaxis should be encouraged. Prophylaxis was not an encouragement for improper sexual intercourse, it was merely a protection against disease, and if venereal disease was on the increase in our country to-day after all the efforts of the different organizations, he thought that every rational means should be taken to head off infections in every possible way. In the extracantonment zones, with the government assistance where law enforcement, quarantine and prophylaxis were used, public health men were of the opinion that venereal disease was reduced to a minimum, and the results were very gratifying. Clinics properly managed were a great assistance, and many thousands of cases were treated beyond the infectious stage, which only went to prove that if these same methods were carried out strenuously in every civilian community, the results would be wonderful. A very important part in the development of this work depended largely upon the sort of cooperation given by the medical profession. If every physician in the United States would take a special personal interest in the control of venereal disease it would go a long way toward the success of the movement. By encouraging local boards of health in reporting, and the internment of infectious cases, and by enlightening the public in their local communities of the havoc which these diseases played upon the moral, physical, and economic life would be of great assistance. A very important point in considering the internment of women was that prostitutes were not the only carriers of venereal infections. In some of the large military venereal hospitals of London, statistics showed that three-fourths of the infections were due to women who were not prostitutes; but who were common carriers, known in that country as amateurs, and it was found the same condition existed in this country in different communities, young girls from fourteen up, living at home, commonly known as private snaps or street-walkers, were the ones that were spreading a big percentage of the infections, and the greatest amount of good was being accomplished among this class of carriers by social workers, women of the welfare league, police matrons, probation and juvenile officers, all of whom should be encouraged in this work, especially the follow-up on carriers after they were released. All cases should be treated. A person suffering from a venereal disease should receive immediate attention just the same as a person injured in an accident.

The Detention and Treatment of Infected Women as a Measure of Control of Venereal Disease in Extracantonment Zones.—DR. W. F. DRAPER, of Richmond, Virginia, said that the detention hospitals were a potent factor in controlling the spread of venereal diseases in extracantonment zones in the following ways: (1) By making it possible to remove a large number of infected immoral women from the community and holding them absolutely apart from the general population for a number of months; (2) By making the chances of isolation for a considerable period of time so great as to discourage immoral women from operating in these areas; (3) By giving a practical demonstration to the community of the high prevalence of venereal diseases among immoral women, and the time and effort necessary in the treatment of these diseases; (4) By actually removing foci of infection by medical treatment. The actual treatment of the women was believed to have been of far less importance in controlling venereal diseases in the extracantonment zones than the other factors

mentioned. None of the women gave the slightest indication of any intention of changing their mode of life. It was what they were accustomed to, what they liked, and what they intended to follow. In this connection the efforts of doctors, nurses and social workers proved of no avail. A period of treatment lasting only a few months was of doubtful efficacy and served only to embitter the patient without in any way detracting from her intention of again resorting to prostitution immediately upon her release from the hospital. It was believed that the period of detention and treatment should be extended for a period lasting from one to four years, thus allowing time for more definite results as to treatment and affording an opportunity for rehabilitation. In cases where the mentality was so low as to preclude the possibility of a life other than one of prostitution it would be an economy and a humanitarian act to commit such individuals to institutional care for life. They were a far greater menace to the happiness and welfare of society than many murderers who were serving life sentences in our prisons. The cost of the detention hospital was the most serious obstacle in the path of its develpoment Few communities were willing, if indeed they were able, to maintain such an institution. It was freely admitted, therefore, that federal aid in the establishment and maintenance of detention hospitals for women would be necessary for a considerable time to come. Detention hospitals not adequately equipped and provided with proper facilities to accomplish the work at hand were worse than none. Jails when used for hospital purposes were an abomination and served only to further degrade and debase the poor unfortunates who came within their confines.

Prenatal Care.—Dr. Sylvester J. Goodman of Columbus, Ohio, stated that prenatal care included the care of women who expected to conceive. The average obstetrician thought it more important to know the technic of applying forceps and of making Cesarean sections than of prenatal care. Pregnant women too often received unsatisfactory information. Books or monographs on the care of pregnancy were not advisable. Diet, to keep the baby small and its bones elastic, was folly. Dancing was harmful. Gentle exercise and pleasant occupation should be encouraged. Harmless drugs might become potent oxytocics during pregnancy The best remedy for vomiting was three months' time. Headache and abnormality of vision demanded attention. The urine must be examined at regular intervals. Blood pressure readings and blood counts had their place. The bowels should move daily and the stool be kept soft. Drastic purgation was harmful. There was no dogmatic diet for pregnant women. The pregnant needed plenty of fresh air. Dress should be light, suited to the weather, and suspended from the shoulders, or lightly from the hips. The care of the breasts was of importance. The vaginal douche had its place. The capacity and shape of the pelvis should be known. Cesareanized women needed hospital care. Attention should also be given to the teeth, luetic and skin diseases, varicose veins, the heart and lungs, mental and nervous diseases, rheumatism and rheumatoid conditions. Pregnancy was no contraindication to surgical treatment of goiter.

The Care of the Bowels During the Puerperal Period.—Dr. Ross McPherson of New York City stated that taking the total number of cases into account, there were 900 who were given routine catharsis and 911 in whom no catharsis was administered. In the 900 who had catharsis, there were 84 who at some time or other in their convalescence developed a temperature of 100.4° twice during twenty-four hours in their puerperium. Of the 911 to whom no catharsis was administered, there were 53 cases who developed the same temperature at the same time or 5.8 per cent. In other words, in approximately 1000 cases of each type the febrile morbidity was about one-half as much in the cases who received no stimulation to the bowels as those who did. When one considered the lessened danger of infection caused by the spreading about the mother's soft parts of loose diarrheic movements, and when one considered the enormous amount of labor saved for the nurses as well as the comfort of the patient, and when one considered further the figures quoted in this series, it gave some intimation of the necessity for active thought on the part of the obstetrician for every move that he made, every drug that he prescribed, and for less habit and more individualization. The writer was far from believing that there was never any necessity for administering a cathartic in the puerperium, quite the contrary, but what he wished to emphasize was the danger and uselessness of routine drugging, and the assigning of certain effects to conditions which had not been shown to be the cause of the symptoms exhibited. Since trying the above treatment in the hospital, he had adopted it in private practice where the results had been equally satisfactory.

A Method of Placing Sutures in Immediate Repair of the Perineum.—Dr. William D. Porter of Cincinnati said that in simple longitudinal tears the usual method was to place the sutures transversely. Place the sutures longitudinally as follows: The torn surfaces being well separated, the needle was carried through the mucous membrane half an inch to the left of the apex of the torn surface, then carried longitudinally under the torn surface, keeping half an inch to the left of the gutter of the tear, the needle was brought out through the skin half an inch to the left of the deepest point in the skin tear. The needle was next removed and placed on the other end of the suture, which was then carried down in a similar manner half an inch to the right of the gutter. The next stitch was placed parallel to the first, and half an inch to the outside. In a complete tear, the first stitch was carried through the skin near the mucocutaneous junction in such a manner as to transfix the end of the torn and retracted sphincter muscle; then under the torn surface parallel with, and near to, the edge of the torn rectal mucous membrane up to the apex of the tear in the septum, and transversely through the septum and down on the other side until the other end of the torn circular muscle was transfixed, and the needle brought out to correspond to the point of entrance. Succeeding sutures were placed parallel to the first.
